Tumor suppressor genes negatively regulate cellular growth and play a critical role in the normal processes of the cell cycle. These genes are also important for DNA repair and cell signaling. The absence of tumor suppressor gene function may lead to dysregulation of normal growth control and malignancy. Loss of function of both copies (alleles) of a tumor suppressor gene is typically required for carcinogenesis. This functional loss can occur via (1) homozygous gene deletion; (2) loss of one allele and mutational inactivation of the second allele; (3) mutational events involving both alleles; or (4) loss of one allele and epigenetic inactivation of the second allele, often involving DNA methylation, which suppresses expression

Basic Molecular Genetics

A glossary of molecular biology terms is presented in [Box 19-1](#).

DNA

The molecular characteristics of deoxyribonucleic acid (DNA) were first described in 1953 ([Watson and Crick, 1953](#)). This molecule serves as the blueprint for determination of structure and function of all living organisms. **DNA comprises three basic components: a pyrimidine or purine base, a sugar (2-deoxyribose), and a phosphate (Fig. 19-1).** The DNA structure exists as a double helix in which one strand of bases is ordered in one direction and the other strand is ordered in the opposite direction. The two strands are held together by hydrogen bonds and are organized

via complementary base pairing. The four bases that primarily constitute DNA are adenine, cytosine, guanine, and thymine. Uracil is substituted for thymine in ribonucleic acid (RNA). **Hydrogen bonding occurs specifically between the purine adenine (A) and the pyrimidine thymine (T) and between the purine guanine (G) and the pyrimidine cytosine (C) (Fig. 19-2).** In the RNA molecule, adenine base pairs with uracil (U).

During the process of replication, each strand of the DNA double helix acts as a template for generation of the new strand of DNA. The precise ordering of DNA base pairs results in a code that is processed ultimately to generate proteins responsible for various cellular functions. Each single-stranded DNA molecule has two nonidentical ends referred to as the 5' (5 prime) and 3' (3 prime) termini. The 5' and 3' numbering refers to the carbon atoms in the deoxyribose sugar. The 5' carbon of one deoxyribose is linked to

BOX 19-1 Glossary of Molecular Biology Terms

Allele: An alternative form of a gene.

Alternative splicing: A mechanism by which variations in the incorporation of a gene's coding regions during mRNA maturation leads to the production of multiple related forms of a gene.

Amplification: Additional copies of a chromosomal sequence; these sequences may include genes and may be extrachromosomal or intrachromosomal.

Aneuploid: Deviation in chromosomal number from the usual diploid state (e.g., tetraploidy)

Annealing: The pairing of two single strands of complementary DNA sequences to form a double helix.

Base pair: The physical relationship between adenine/thymidine and guanine/cytosine within the double helix of DNA. Abbreviated as *bp*, it provides the unit of measurement for DNA. Each base pair is stabilized by hydrogen bonds.

cDNA: A segment of DNA complementary to an RNA sequence.

Centromere: An essential structural element of chromosomes consisting of repetitive, noncoding DNA to which the spindle microtubules attach during mitosis.

Chromosome: A distinct segment of linear DNA containing a large number of genes. In humans, there are 23 such segments, each containing hundreds to thousands of genes.

Codon: Three sequential nucleotides in protein coding genes that specify a particular amino acid in the protein or a STOP translation signal.

Deletion: The removal of a segment of DNA, with rejoining of the ends.

Diploid: A set of chromosomes containing two complete copies of the organism's genomic DNA.

Dominant: Allele determining the phenotypic manifestation of a gene.

Endonuclease: An enzyme that cuts DNA or RNA within the nucleotide chain.

Epigenetic: Nongenetic information, such as methylation or acetylation of histone proteins, that modifies gene expression.

Exon: A sequence of DNA that is represented with a complementary RNA sequence, also known as the coding sequence.

Expression vector: A vector designed to encode a particular DNA sequence or gene for transcription and translation into RNA or protein.

FISH: Fluorescence in situ hybridization. A technique in which a fluorescently labeled nucleic acid probe is hybridized to its complementary target sequence in the genome allowing localization and enumeration of the target.

Frameshift mutation: A deletion or insertion of DNA that shifts the normal codons into a different order for translation into protein.

Gene: A segment of DNA that contributes to the formation of a protein, including both the introns (noncoding regions) and the exons (coding regions) and the regulatory regions preceding and following the coding regions.

Genetic code: The correspondence between triplets of DNA or RNA (codons) and amino acids making up proteins.

Genotype: The genetic makeup of an organism as reflected in its DNA sequence.

Haplotype: A group of alleles in relative close proximity on a chromosome that are inherited together.

Hemizygote: Having only one copy of a gene owing, for example, to the loss of chromosomal material or an entire chromosome.

Heterozygote: Having two different copies (alleles) of a gene.

Homozygote: Having two identical copies (alleles) of a gene.

Hybridization: The physical pairing of complementary RNA or DNA sequences.

Intron: A segment of DNA that is transcribed but is removed by the splicing together of the exons on either side; part of the noncoding sequences of a gene.

Karyotype: A catalog of all the chromosomes within a particular cell. Typically accomplished by isolation and staining of metaphase chromosomes.

Linkage: The tendency for genes in proximity to one another on a chromosome to be inherited together.

Locus: The position of a particular gene on a particular chromosome.

Loss of heterozygosity (LOH): Deletion or mutation of a gene creating a hemizygous state or, if the remaining allele is duplicated, a homozygous state. In cancers arising in cancer predisposition syndromes caused by an inherited gene mutation, the remaining wild-type allele is often lost via LOH.

Methylation: The addition of a methyl group to a molecule. Methylation of the nucleotide cytosine in the promoter regulatory region of a gene is often associated with decreased transcription of that gene.

MicroRNA (miRNA): Small, single-stranded RNA molecules 21 to 23 nucleotides in length that function to regulate negatively transcribed genes for which they have sequence complementarity.

Mutation: Any change in the sequence of genomic DNA.

Northern blotting: A technique of transferring RNA from an agarose gel to a nitrocellulose filter for hybridization with a complementary DNA.

BOX 19-1 Glossary of Molecular Biology Terms—cont'd

Oncogenes: Genes that encode for proteins that have the ability to transform normal cells into cancerous cells.

Phenotype: The appearance or function of an organism, reflecting the contributions of the genotype and the environment.

Ploidy: The number or copies of entire chromosome complements (genomes) within a cell; diploid has two copies, triploid has three copies, tetraploid has four copies, and so forth.

Point mutation: A change in a DNA sequence involving a single base pair.

Polymerase chain reaction (PCR): A technique using sequential temperature cycles favoring DNA denaturation, annealing of primer sequences, and primer extension with DNA polymerase to amplify a large number of copies of a particular sequence of DNA. This technique can be used to detect very small amounts of DNA by creating a huge number of identical copies.

Polymorphism: A difference in normal DNA sequence between individuals. It can be a repetitive element or a single nucleotide polymorphism (SNP).

Promoter: The region of DNA in a gene where RNA polymerase binds and gene transcription begins. This region is often the sequence of DNA 100 to 500 base pairs immediately before the initiation site of the protein coding portion of the gene.

Recessive: An allele that is not represented phenotypically in the presence of a dominant allele.

Reporter gene: A gene encoding for a new or foreign protein that can easily be detected. For example, the luciferase gene, encoding the light-producing proteins of the firefly, is introduced into cells that do not express this gene.

Restriction enzyme: Recognizing specific short sequences of DNA (e.g., four or six base pairs), these enzymes cut the DNA at a particular location.

Silent mutation: An alteration in a DNA sequence that does not change the protein product of the gene.

Small interfering RNA (siRNA): Small double-stranded RNA molecules 20 to 25 nucleotides in length that promote degradation of mRNA molecules to which they have complementarity, down-regulating expression of the corresponding gene. Often employed by researchers as a means of reducing expression of specific genes.

Southern blotting: A technique of transferring denatured DNA from an agarose gel to a nitrocellulose filter for hybridization with cDNA.

Splicing: The removal of introns (spliced out) and the connection of exons (spliced together) in mRNA.

Telomere: An essential structural element of chromosomes consisting of repetitive, noncoding DNA and associated telomere-specific binding proteins that cap and stabilize the chromosomal termini.

Transcription: Synthesis of RNA on a DNA template.

Transfection: The introduction of DNA sequences into a cell.

Transgenic animals: Animals created by the introduction of new DNA into the germline (into the egg).

Translation: Synthesis of protein from the mRNA template.

Vector: A plasmid, bacteriophage, or virus that carries new DNA into a cell. Vectors are often designed to produce large amounts of protein encoded by the gene within the host cell.

Figure 19-1. The nucleic acid alphabet consists of four bases: the purines adenine (A) and guanine (G) and the pyrimidines thymine (T) and cytosine (C). Uracil (U) is substituted for thymine in the case of RNA. The combination of a base and a sugar (deoxyribose) is referred to as a *nucleoside*.

Figure 19-2. The combination of a sugar phosphate group and a base constitutes a *nucleotide*. The double helix is made from two polynucleotide chains, each of which consists of a series of 5'- to 3'-sugar phosphate links that form a backbone from which the bases protrude. The double helix maintains a constant width because purines always face pyrimidines in complementary A-T and G-C base pairs.

the 3' carbon of another deoxyribose by a phosphate group. Each strand ends with part of the sugar ring exposed based on these connections.

Transcription

Transcription is the first step in converting information encoded in DNA into protein. During the process of transcription, linear DNA sequence is converted to linear RNA (messenger RNA [mRNA]). mRNA is later translated into a linear set of amino acids that form a functional protein (Fig. 19-3). RNA polymerase II is the enzyme that synthesizes mRNA, which is complementary to the DNA template. This primary strand of RNA is called a pre-mRNA and contains both protein coding sequences (exons) and intervening noncoding sequences (introns).

The pre-mRNA molecule undergoes three major modifications: 5' capping, 3' polyadenylation, and RNA splicing. These processes occur in the nucleus before the RNA molecule is translated into protein. RNA splicing is a dynamic process that can result in the formation of different peptide sequences having different functional properties. For example, alternatively spliced versions of the androgen receptor (AR) lacking the androgen binding domain have been identified in prostate cancer cells. Such AR splice variants are active in the absence of bound ligand and may contribute to the emergence of prostate cancer refractory to androgen ablative therapies (Dehm et al, 2008; Guo et al, 2009a; Hu et al, 2009). **Alternative RNA splicing is how a single gene can encode for multiple unique proteins by including or excluding certain exons in the mature mRNA transcript (Sharp, 1987).** The sequences contained within introns are not essential for protein synthesis; introns are spliced out and exons are spliced together to generate the functional mRNA.

Protein Synthesis

Translation of mRNA into protein occurs in the cytoplasm where ribosomes are located. The mRNA message is translated in segments of three adjacent nucleotides called a codon. Each codon is translated into 1 of 20 amino acids (Fig. 19-4). From the four bases

Figure 19-3. During transcription, a section of one DNA strand or the other is used as a template for the synthesis of messenger RNA. This synthesis always occurs in a 5'-to-3' direction.

found in RNA, 64 different codons can be generated. Because of redundancy, more than one codon can encode for a single amino acid (Fig. 19-5). Genetic mutations or alterations can have a profound effect on protein translation of mRNA. For example, a single base insertion or deletion results in a frame-shift mutation and often results in a nonfunctioning protein product. In contrast, a single base substitution may or may not result in a change in the amino acid sequence, which may or may not alter protein function.

Two other forms of RNA are important for protein translation: transfer RNA (tRNA) and ribosomal RNA (rRNA). tRNA is a small (75 to 85 bases long) adapter molecule that is covalently linked to a single amino acid at one end and an anticodon in the middle of the RNA chain. The anticodon comprises three nucleotides that are complementary to the mRNA codon representing a particular amino acid. rRNA comprises approximately 80% of the RNA within a cell and makes up part of the ribosome, which is the macromolecular structure responsible for protein synthesis.

The three major stages of protein synthesis are initiation, elongation, and termination. Initiation is frequently the rate-limiting step in translation (Merrick, 1992). During the process of initiation, the 40S ribosome binds to mRNA and forms an initiation complex that binds a tRNA with an amino acid attached. All new proteins start with methionine because the initiation codon is AUG. During elongation, amino acids are sequentially added to the peptide chain, and the ribosome moves along the mRNA chain similar to beads on a string. Elongation is the most rapid phase of protein synthesis. For any given mRNA transcript, multiple

Figure 19-4. During transcription, the coding strand conveys its message through the template strand to make messenger RNA that is eventually translated into polypeptides by ribosomes. The relationship between DNA sequence and corresponding protein is called the **genetic code**, which is read in nucleotide triplets or codons specifying amino acids or protein translational start and stop signals. The code is degenerate, in that multiple codons may code for the same amino acid.

First base	Second base				Third base
	U	C	A	G	
U	Phenylalanine	Serine	Tyrosine	Cysteine	U
	Phenylalanine	Serine	Tyrosine	Cysteine	C
	Leucine	Serine	Stop	Stop	A
	Leucine	Serine	Stop	Tryptophan	G
C	Leucine	Proline	Histidine	Arginine	U
	Leucine	Proline	Histidine	Arginine	C
	Leucine	Proline	Glutamine	Arginine	A
	Leucine	Proline	Glutamine	Arginine	G
A	Isoleucine	Threonine	Asparagine	Serine	U
	Isoleucine	Threonine	Asparagine	Serine	C
	Isoleucine	Threonine	Lysine	Arginine	A
	Methionine	Threonine	Lysine	Arginine	G
G	Valine	Alanine	Aspartic acid	Glycine	U
	Valine	Alanine	Aspartic acid	Glycine	C
	Valine	Alanine	Glutamic acid	Glycine	A
	Valine	Alanine	Glutamic acid	Glycine	G

Figure 19-5. RNA codon table. The 20 amino acids found in proteins are listed. All 64 possible 3-letter combinations of the RNA coding units U, C, A, and G are used to encode an amino acid or one of the three stop codons. Note: The codon AUG codes for methionine and serves as an initiation site (the first AUG in the messenger RNA coding region where translation in protein is initiated).

ribosomes can simultaneously move along the chain to generate new polypeptides (Rich et al, 1963). Termination is the last stage of protein synthesis and is signaled by one of three stop codons (Tate and Brown, 1992).

Chromosomes and Gene Structure

The long strands of DNA responsible for the genetic makeup of eukaryotic cells (the genome) are organized together with

specialized proteins to form chromosomes. Eukaryotic cells contain large linear chromosomes that are packaged by histone proteins into a condensed structure called *chromatin*. The local chromatin structure has a great impact on gene expression and varies depending on the specific cell type. During interphase, chromatin can be classified into two forms. Euchromatin consists of DNA that is actively being expressed as protein, whereas heterochromatin consists of inactive DNA that may serve a structural support role.

Figure 19-6. Knudson's hypothesis was that inactivation of the same gene was responsible for both sporadic and hereditary malignancies. Patients with sporadic tumors had two normal copies of the gene, and the sporadic tumors required inactivation of both copies of the gene. Patients with hereditary tumor syndromes were born with only one functioning copy of the gene of interest, and the hereditary tumors required inactivation of only one copy.

of the gene. Classic tumor suppressor genes discussed later in this chapter are the retinoblastoma gene (*RB1*) and the *TP53* gene (see [Cell Cycle Deregulation](#)).

The “two-hit” hypothesis was first proposed in cases of retinoblastoma, which required mutations in both alleles for disease manifestation (Knudson, 1971). This requirement is due to the fact that if just one allele is inactivated, the remaining allele could produce sufficient amounts of the correct protein to maintain the normal state (Fig. 19-6). However, specific types of mutations in certain genes may not follow this two-hit rule and can function in a dominant negative capacity when mutated, inhibiting the function of the normal protein from the unaltered allele. An example is when two or more of the same protein molecules act together (e.g., dimerization), as is the case for *TP53* (Baker et al, 1990). Alternatively, deletion or mutation of a single allele may result in insufficient protein production (haploinsufficiency) causing an increased carcinogen susceptibility as in the case of the *CDKN1B* (p27Kip1) gene (Fero et al, 1998).

Oncogenes

Oncogenes are positively associated with cellular proliferation and are the mutated form of normal genes (proto-oncogenes). Two oncogenes that have been found to be overexpressed in various cancers include *MYC* and *MET* (Wong et al, 1986; Bottaro et al, 1991). The proto-oncogene *MYC* encodes an early-response gene product that is a transcription factor responsible for regulating cellular proliferation. Amplification of *MYC* is a frequent event in prostate cancer, and expression of *MYC* in human prostate epithelial cells has been associated with immortalization (Gil et al, 2005).

Hepatocyte growth factor acts through a receptor that is encoded by the proto-oncogene *MET* (Bottaro et al, 1991). Increased expression of *MET* has been reported in renal cell carcinoma (RCC) and is more frequent in higher grade cancers (Pisters et al, 1997). Missense mutations of the *MET* proto-oncogene may also result in constitutive activation of the *MET* protein in tumors associated with hereditary RCC (Schmidt et al, 1997).

Mechanisms by which a proto-oncogene can be converted to an activated oncogene are via (1) mutation of the proto-oncogene resulting in an active form of the gene product, (2) gene amplification, and (3) chromosomal rearrangement. A mutation occurring within the protein coding sequence of a gene can lead to a continuous proliferation signal from the mutant protein. For example, mutation of the proto-oncogene *ERBB*, which encodes

for the epidermal growth factor receptor (EGFR), results in expression of a receptor that is constitutively active (Downward et al, 1984). Errors that occur during chromosomal replication may result in gene amplification and aneuploidy. Such an increase in gene copy number often results in an increased number of mRNA transcripts and overproduction of the corresponding protein. For example, certain types of bladder cancer overexpress *MYC* by this mechanism (Christoph et al, 1999). Immunohistochemical (IHC) staining of bladder cancer specimens has demonstrated overexpression of *MYC* protein in more than half of papillary and invasive tumors (Schmitz-Drager et al, 1997). Finally, chromosomal structural rearrangements such as translocation events can result in the formation of an oncogene; for example, genetic rearrangement leads to the fusion of a portion of the *TMPRSS2* gene and the *ERG* oncogene in a large proportion of prostate cancers (Tomlins et al, 2005).

KEY POINTS: TUMOR SUPPRESSOR GENES AND ONCOGENES

- Mutations in DNA can lead to changes in protein function or expression that increase the potential for cancer initiation, progression, or metastasis.
- Tumor suppressor genes normally negatively regulate and control cellular growth. Oncogenes normally promote cell growth.
- Loss of tumor suppressor gene function can occur primarily by (1) homozygous deletion, (2) loss of one allele and mutational inactivation of the second allele, (3) mutational events involving both alleles, and (4) loss of one allele and epigenetic inactivation of the second allele.
- Certain tumor suppressor genes do not follow the “two-hit” hypothesis and may be inactivated via dominant negative mutations or haploinsufficiency.
- Proto-oncogenes can be converted to oncogenes by (1) mutation of the proto-oncogene resulting in an activated form of the gene, (2) gene amplification, and (3) chromosomal rearrangement.

CELL CYCLE DEREGLATION

Apart from development and growth, cell division is tightly regulated such that the production of new cells precisely balances loss of cells during normal wear and tear, maintaining tissue and organ homeostasis. In contrast to single-celled eukaryotes, individual human cells are not allowed to make autonomous decisions regarding their proliferation. Rather, a complex series of external growth inhibitory and growth stimulatory signals are integrated by the cell, resulting in either cell division or quiescence. In cancer, activated oncogenes and inactivated tumor suppressor genes alter the balance between these signals such that net proliferation is continuously favored.

Quiescent cells are considered to be out of cycle, in a reversible state known as “*G*₀” that is the default state for most cells. When signaled to proliferate, cells activate their cell cycle machinery, initiating an orderly, unidirectional series of events resulting in duplication of the cell's genome during the DNA synthetic phase (S phase), followed by segregation of each genomic complement to each of two resulting daughter cells, a process referred to as mitosis (M phase). These two critical phases are separated by two so-called “gap” phases (*G*₁ and *G*₂). Throughout the cell cycle, which takes approximately 24 hours to complete, each step depends on completion of the prior step before progressing further (Hartwell et al, 1974). In addition, checkpoint mechanisms closely monitor DNA integrity and certain critical cell cycle events. If problems are detected (e.g., DNA damage), the cell cycle is paused to allow for repair (Hartwell and Weinert, 1989). If repair is impossible,

normal cells often commit cellular suicide through an active process termed *apoptosis*. Many oncogenes and tumor suppressors exert their effects by interfering with cell cycle checkpoints and apoptotic pathways, allowing cancer cells to divide continuously and accumulate. Loss of ability to respond appropriately to damaged DNA is particularly dangerous because it fosters genetic instability, a key attribute of cancer cells. Loss of DNA damage checkpoint controls results in an increased mutation rate, accelerating the mutation of cancer-associated genes and contributing to carcinogenesis and disease progression (Bartek et al, 1999).

Additional details of the eukaryotic cell cycle (cyclin-dependent kinases and cyclins, cell cycle entry, the retinoblastoma protein and the restriction point, S phase, mitosis, and cell cycle checkpoints) can be found on the Expert Consult website.

Retinoblastoma Protein and Genitourinary Malignancies

The retinoblastoma susceptibility protein, RB1 (formerly pRb), plays a central role in controlling the R-point—a decision point in late G₁, beyond which an irreversible commitment to divide is made. The inappropriate, continuous proliferation of cancer cells is largely due to a loss of R-point control, typically the result of functional inactivation of the RB1 pathway (Pardee, 1989). RB1 gene mutations have been identified in approximately one third of bladder tumors (Horowitz et al, 1990), and reintroduction of the RB1 gene into bladder carcinoma cell lines has been found to inhibit cell growth in vitro and tumor formation in vivo (Takahashi et al, 1991). Altered expression of RB1 protein also has been identified in approximately one third of bladder carcinomas (Logothetis et al, 1992), and altered expression has been correlated with higher stage disease and decreased patient survival (Cordon-Cardo et al, 1992).

Prostate carcinoma has not been as strongly linked to RB1. Although RB1 mutations are present in 10% to 30% of prostate cancer specimens (Bookstein et al, 1990; Kubota et al, 1995), decreased expression is not consistently identified with high-risk patients or recurrent disease (Kibel and Isaacs, 2000). In other studies, no correlation was found between expression and grade or stage (Ittmann and Wiczorek, 1996), but Theodorescu and colleagues (1997) reported that low RB1 protein expression correlated with decreased disease-specific survival in univariate and multivariate analysis.

Renal carcinoma has not been clearly linked to RB1. RB1 is rarely inactivated in renal carcinoma cell lines or tumors (Ishikawa et al, 1991). Analysis of clinical specimens has not demonstrated a clear association between prognosis and RB1 expression (Lipponen et al, 1995).

Cyclin-Dependent Kinase Inhibitors

The temporal sequencing of events occurring throughout the cell cycle is affected by cyclin-dependent kinases (cdks), a highly conserved set of protein kinases (Meyerson et al, 1992). The cdks phosphorylate specific protein substrates involved in executing the phase-specific activities of the cell cycle. The enzymatic activities of the cdks depend on cyclins, so named because their abundances are tightly linked to specific phases of the cell cycle, during which they physically associate with and activate the enzymatic activity of the cdks (Fig. 19-7) (De Bondt et al, 1993; Jeffrey et al, 1995). Another group of proteins termed *cyclin-dependent kinase inhibitors* (CDKIs) bind to and directly inhibit cdk activity or their activating phosphorylations (Peter and Herskowitz, 1994; Sherr and Roberts, 1995). Although cyclins play major regulatory roles in orchestrating cdk activities, cdks are subject to additional levels of control, and these processes are commonly altered in cancer cells. CDKIs belong to either of two different classes, the Cip/Kip family, which includes the proteins CDKN1A (p21), CDKN1B (p27), and CDKN1C (p57), and the INK4 (*inhibit cdk4*) family, which includes INK4B (p15), INK4A (p16), INK4C (p18), and INK4D (p19). The Cip/Kip proteins have broad actions, able to inhibit multiple cyclin-cdk complexes throughout the cell cycle (Clurman and Porter,

Figure 19-7. Schematic drawing of the cell cycle. Sequential activation of cyclin-cdk complexes is critical to the orderly progression of replication of the cell.

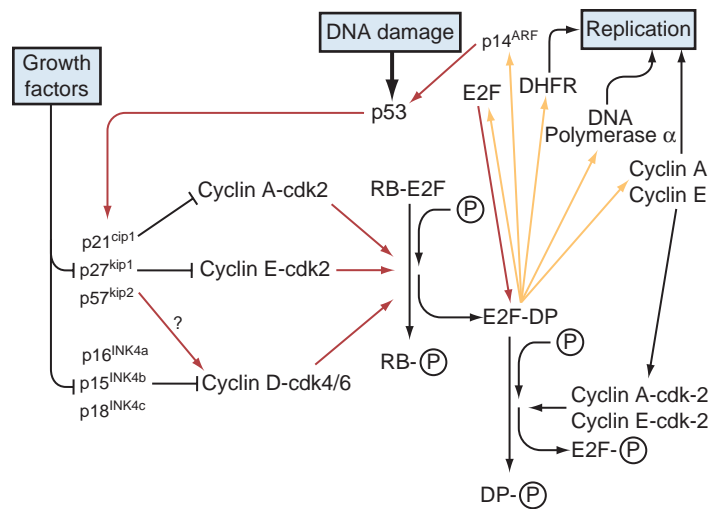

Figure 19-8. Schematic representation of the stimulatory and inhibitory cascade at the G₁/S boundary. This finely tuned system takes advantage of multiple negative and positive feedback loops.

1998). The INK4 proteins are more restricted in their activities, inhibiting cdk4-containing and cdk6-containing complexes; they are critical regulators of the R-point and the G₁/S transition because they can block RB1 phosphorylation (Fig. 19-8). The cell uses increased expression and accumulation of CDKIs as a means of halting the cell cycle in response to various stresses. For example, p21 expression is increased in response to DNA damage (el-Deiry et al, 1993). CDKIs function in nonstress situations as well. For example, p27 levels are high in quiescent cells, and all of the Cip/Kip proteins appear to play some role in maintenance of the G₀ state in terminally differentiated cells (Halevy et al, 1995; Matsuo et al, 1995; Parker et al, 1995).

Among the INK4 family, inactivating mutations and abnormal gene promoter methylation of p15 and p16 have been strongly implicated in cancer in general (Kamb et al, 1994; Hiram and Koeffler, 1995) and specifically in GU malignancies (Cairns et al, 1995; Herman et al, 1995). The best studied of the INK4 proteins is p16. The p16 protein binds to cdks 4 and 6 and inhibits their interaction with cyclin D1 that normally mediates passage through the G₁ phase of the cell cycle by phosphorylation of the RB1 protein (Serrano et al, 1993). The INK4A gene encoding p16 was initially found to be mutated and deleted in a wide variety of tumors

Cyclin-Dependent Kinases and Cyclins

The temporal sequencing of events occurring throughout the cell cycle are affected by a highly conserved set of serine-specific and threonine-specific protein kinases termed cyclin-dependent kinases (cdks) (Meyerson et al, 1992). The cdks phosphorylate specific protein substrates involved in executing the phase-specific activities of the cell cycle. As their name implies, the enzymatic activities of the cdks depend on a class of regulatory proteins called *cyclins*, of which there are 12 known in mammals (Morgan, 1995). The abundance of specific cyclins within the cell is highly dynamic and tightly linked to specific phases of the cell cycle, during which they physically associate with and activate the enzymatic activity of the cdks (see Fig. 19-7) (De Bondt et al, 1993; Jeffrey et al, 1995). Depending largely on the transitory presence of particular cyclins, which are rate-limiting, specific cyclin/cdk complexes form and act during restricted periods within the cell cycle to initiate and regulate the events required during these precise phases, after which each cyclin is typically degraded via polyubiquitination of specific lysine residues that serve as the signal for proteosomal degradation, inactivating its cdk partner (Sherr, 1993; van den Heuvel and Harlow, 1993). The cdks are also regulated by specific sites of phosphorylation on the cdks themselves (Lundgren et al, 1991). Finally, a group of proteins termed *cyclin-dependent kinase inhibitors* (CKIs) can bind to and inhibit cdk activity directly or their activating phosphorylations (Peter and Herskowitz, 1994; Sherr and Roberts, 1995). Although cyclins play major regulatory roles in orchestrating cdk activities, cdks are subject to additional levels of control, and these processes are commonly altered in cancer cells as well.

Cell Cycle Entry

Under normal conditions, a cell is induced to proliferate when the balance between growth-stimulatory signals received from its environment (e.g., soluble growth factors in the extracellular space) outweighs growth inhibitory signals (e.g., transforming growth factor- β). If a cell in the G_0 state is stimulated to proliferate, it will proceed into G_1 , the first gap phase of the active cell cycle, during which sufficient macromolecules and organelles are synthesized to support cell replication. Growth stimulatory signaling pathways (e.g., the Ras/Raf/MEK pathway) promote expression of the main G_1 cyclins, cyclin D and cyclin E, leading to their association with cdk4 and cdk6 kinases, activating these cdks (Baldin et al, 1993; Winston and Pledger, 1993; Sherr et al, 1994). Throughout early and mid G_1 , progression through the cell cycle remains sensitive to external signals, largely because persistent mitogenic stimulation is required for sustained expression of cyclin D (Matsushime et al, 1991).

Retinoblastoma Protein and Restriction Point

Because of the dependence of cyclin D on the continued presence of mitogens and other favorable conditions (e.g., attachment to the substratum), the cell cycle remains responsive to external signals throughout early and mid G_1 (Guadagno et al, 1993). However, if the decision is made in late G_1 to continue on with cell division, the subsequent phases of the cell cycle (S, G_2 , and M) proceed in an autonomous fashion. This key point in time in late G_1 , after which the cell cycle becomes insensitive to extracellular signals, is termed the *restriction point* (R-point) and is highly regulated (Pardee, 1974).

The retinoblastoma susceptibility protein, RB1 (pRb), plays a central role in controlling the R-point, and the inappropriate, continuous proliferation of cancer cells is largely due to a loss of R-point control, typically the result of functional inactivation of the Rb pathway (Pardee, 1989). RB1 is a substrate of G_1 cyclin/cdk complexes, and its activity is critically dependent on its phosphorylation state (Buchkovich et al, 1989; Mittnacht et al, 1994; Sherr, 1994). In nondividing cells, RB1 is unphosphorylated, and in this state RB1 physically associates with members of the E2F

family of transcription factors, inhibiting their transcriptional activation of target genes required for cell cycle progression into S phase (Lai et al, 1999b). In addition, RB1 recruits proteins such as histone deacetylases to E2F target genes promoting the formation of repressive heterochromatin at these sites, and RB1 itself may play a role in maintaining this repressive chromatin state, further suppressing E2F target genes (Lai et al, 1999a; Gonzalo and Blasco, 2005). However, during G_1 , RB1 becomes progressively phosphorylated on eight different sites by cyclin D-cdk4/6 and cyclin E-cdk2 complexes, creating hyperphosphorylated RB1, causing its dissociation from E2F (see Fig. 19-8). The liberated E2F proteins, of which there are at least seven, heterodimerize with one of three DP subunits (DP1-3) and activate transcription of target genes, including essential S phase genes (e.g., DNA polymerase and S phase cyclins) (Dyson, 1998). When the cell cycle is complete, RB1 returns to its unphosphorylated state, once more suppressing E2F until cell division is signaled again (Ludlow et al, 1993).

There are many ways, both direct and indirect, in which cancer cells inactivate function of RB1, including mutation or deletion of the RB1 gene itself; silencing of the RB1 gene via promoter DNA hypermethylation; overexpression of proteins such as cyclin D and E2F (in some cases as a result of increased copy number of the gene, or gene amplification), and mutational inactivation, deletion, or promoter methylation of genes encoding specific cdk inhibitors. It has been suggested that RB1 or components of the regulatory pathway with which it is associated (e.g., cyclins D and E, cdk4, E2F, p16 and p27) are likely to be altered in virtually all human cancers (Sherr, 1996; Hanahan and Weinberg, 2000).

Cell Cycle Progression through S Phase

During S phase, a normal cell replicates its diploid genome only once. S phase genes are activated as a result of cyclin A replacing cyclin E to form cyclin A-cdk2 complexes in early S phase and later by cyclin A associating with cdk1 forming cyclin A-cdk1 complexes in late S phase (Girard et al, 1991; Pagano et al, 1992). On completion of S phase, cyclin A-cdk2 phosphorylates E2F-DP heterodimers, terminating activity of E2F (Dylnacht et al, 1994). At the end of S phase, cyclin B replaces cyclin A, forming cyclin B-cdk1 complexes, which move the cell into the second gap phase of the cell cycle, G_2 , and on into mitosis (Pines and Hunter, 1989).

Mitosis

During mitosis, the two genomic complements present after S phase are precisely partitioned into what will become two separate daughter cells. The proper functioning of many of the proteins participating in mitosis depends on phosphorylation of these substrates by cyclin B-cdk1. Early in mitosis, the chromosomes condense through the activity of condensin proteins. Each chromosome is tightly associated along its length with its corresponding S phase copy, termed the *sister chromatid*, via cohesin proteins. Also during this time, two structures called centrosomes, which act as microtubule organizers, migrate to opposite poles of the nucleus and assemble spindle microtubules that radiate through the nucleus and attach to the condensed chromosomes at constriction sites termed *centromeres* via complex protein matrices termed *kinetochores*. The nuclear envelope and supporting intermediate filament proteins, the nuclear lamins, dissociate in response to phosphorylation by cyclin B-cdk1. Balanced tension along the spindle microtubules causes all of the chromosomes to align along the cell midline, creating a hallmark stage of mitosis termed *metaphase*. When all metaphase chromosomes are properly aligned, microtubule-associated motors on the spindle microtubules pull each diploid chromosome complement apart toward the centrosomes at opposite poles, a key mitotic event termed *anaphase*. Lastly, two new nuclei are assembled around the two separated chromosome complements, which decondense, and two separate daughter cells are formed in a cell-splitting process termed *cytokinesis*.

Mitotic abnormalities are commonly seen in human cancers and were noted by Hanseman in the late 1800s, soon after the

discovery of chromosomes. In 1914, the eminent German biologist Boveri proposed that such abnormalities might underlie tumor formation (Harris, 2008).

G₁/S Checkpoint

The expression of cyclin D during G₁ depends on the integration of both proliferative and antiproliferative signals received from the extracellular environment (e.g., mitogens, nutrient and oxygen availability). The cell does not fully commit to division unless it receives a sustained signal to do so and conditions remain favorable (Matsushime et al, 1991).

A critical contributor to the G₁/S checkpoint is the TP53 tumor suppressor protein. TP53 is a pleiotropic transcription factor that receives signals from multiple types of cell stress and damage and, in response, activates genes that function variously in cell cycle arrest, DNA damage repair, and apoptosis (programmed cell death), highlighting the link between cell cycle arrest and DNA repair (see Fig. 19-9) (Elledge, 1996). DNA damage has relevance for the G₁/S checkpoint because a normal cell would not wish to proceed to S phase if the genomic template DNA is damaged; intact checkpoint controls represent important antitumor mechanisms acting to limit the proliferation of cells bearing potentially oncogenic mutations. During the cellular response to DNA damage, specific kinases are activated that phosphorylate the TP53 protein protecting it from hdm2 ubiquitin ligase-mediated degradation (Momand et al, 1992). The accumulated TP53 protein undergoes further modifications that serve to activate it and facilitate its translocation to the nucleus, where it induces various checkpoint and DNA repair proteins, including CDKN1A (p21) and 14-3-3-sigma, which cause cell cycle arrest by inactivating or sequestering G₁ cdk complexes (Giaccia and Kastan, 1998). If the cell cannot arrest growth or repair the DNA damage, TP53 often induces apoptosis (Levine, 1997).

S Phase Arrest

Although S phase is not considered to have a checkpoint per se, such as the checkpoints recognized during G₁/S and G₂/M phases, the cell does maintain the ability to arrest the cell cycle and repair DNA damage through two mechanisms, both mediated through the ataxia-telangiectasia-mutated (ATM) kinase. First, in response to genotoxic insults, Cdc25A is targeted for destruction through an ATM-dependent cascade, resulting in a rapid decrease in Cdc25A levels. Because Cdc25 family members normally activate cdk2, the loss of Cdc25A maintains cdk2 in its inactive form. This cascade pauses the cell in S phase, ostensibly to allow time for DNA repair (Bartek et al, 2004).

The second mechanism mediated by ATM in response to DNA damage is phosphorylation of DNA repair enzymes (see DNA Repair Mechanisms). These two parallel pathways further highlight the interaction between DNA repair and checkpoint control. S phase control in response to DNA-damaging agents is the last opportunity to repair DNA damage before replication (Falck et al, 2002; Pichierri and Rosselli, 2004).

G₂/M Checkpoint

The G₂/M checkpoint is a second major point of control during cell division. In contrast to the G₁/S checkpoint, which responds to various extracellular signals in addition to DNA damage, the G₂/M checkpoint appears to be similar to S phase arrest and responds only to DNA damage. It serves as an important monitor of DNA replication errors (Weinert, 1997; Bartek et al, 1999).

DNA damage secondary to radiation is believed to induce G₂/M arrest through ATM. ATM activates CHEK1 and CHEK2 kinases in response to DNA damage, and these inactivate the Cdc25 family proteins through phosphorylation, which causes 14-3-3 sigma to bind and sequester it (Hermeking et al, 1997; Sanchez et al, 1997).

It has become apparent that, at least in part, G₂/M arrest may also be mediated by TP53 and the BRCA1 tumor suppressor (Bunz et al, 1998; Xu et al, 2001). Transcriptional upregulation of cell cycle inhibitors (e.g., p21, GADD45, 14-3-3 sigma) by TP53 helps maintain the cell in G₂/M arrest (Nyberg et al, 2002). As a result, TP53 appears to mediate both G₁/S and G₂/M arrest, consistent with its critical role in preserving genomic integrity.

Mitotic Arrest—Spindle Assembly Checkpoint

As detailed earlier, one of the key events in mitosis is the proper attachment of every chromosome to the spindle microtubule apparatus. It is critical that all chromosomes are attached before proceeding into anaphase, where the chromosome complements are pulled apart. Failure of one or more chromosomes to attach leads to chromosome nondisjunction, wherein one daughter cell receives an extra copy of the chromosome, becoming trisomic for that chromosome, while the other daughter cell receives one copy too few, becoming monosomic. Both cases are abnormal and fall under the category of aneuploidy, a nearly universal characteristic of human solid tumors. Gene expression patterns often correlate with gene copy number, and it has been proposed that aneuploidy may be a major contributor to cancer initiation and progression (Duesberg et al, 1999; Duesberg, 2005). The mitotic checkpoint (spindle assembly checkpoint) apparatus monitors chromosome attachment and receives a “not ready” signal from any unattached chromosomes, preventing activation of the anaphase-promoting complex, blocking the transition from metaphase to anaphase until all chromosomes are attached (Chan et al, 1999; Holland and Cleveland, 2009). Although mutations have been identified in specific mitotic checkpoint genes, such as *hBUBR1*, in some cancers (Cahill et al, 1998), subsequent studies have shown these to be relatively rare (Wang et al, 2008b). Additional studies have found aberrant expression levels of mitotic checkpoint proteins, which may better explain the mitotic instability frequently observed in cancer cells (Yuan et al, 2006), including reports of reduced levels of the checkpoint proteins MAD1 and MAD2 in RCC (Pinto et al, 2007) and reduced MAD2 in testicular cancer (Fung et al, 2007).

including bladder and kidney (Kamb et al, 1994). Subsequent analysis demonstrated that inactivation often occurs by DNA hypermethylation at the *INK4A* promoter—an alternative, epigenetic method of gene inactivation (Merlo et al, 1995).

The *INK4A* gene is frequently inactivated by deletion in bladder carcinomas (Cairns et al, 1995; Williamson et al, 1995). Despite its proximity, the *INK4B* gene was ruled out as the primary tumor suppressor at this site because it was not within the deletion interval. A study by Orlow and colleagues (1999) found that deletion and methylation of the gene encoding p16 occurred frequently in superficial bladder carcinoma, but only deletions that affect genes encoding both p16 and p14, which are located at the same locus, correlated with a decrease in disease-free survival. In contrast to bladder cancer, mutational inactivation of *INK4* family members appears to be rare in prostate carcinoma. However, inactivation of *INK4A* by promoter hypermethylation has been implicated in prostate cancer. Herman and associates (1995, 1996) demonstrated *INK4A* hypermethylation in 60% of prostate cancer cell lines, whereas *INK4B* was rarely inactivated. However, these results are tempered by the fact that silencing of the *INK4A* gene by promoter hypermethylation often occurs during the establishment of cell lines in vitro.

Despite the critical role that Cip/Kip family members play in G₁/S cell cycle arrest, they are rarely mutated in a wide variety of malignancies, including GU tumors, and there are only rare reports of promoter hypermethylation (Shiohara et al, 1994; Kawamata et al, 1995). However, expression of this family of CDKIs plays an important role in cancer in general (Catzavelos et al, 1997; Loda et al, 1997; Yatabe et al, 1998) and in GU carcinomas in particular. Stein and associates (1998) found increased expression of *CDKN1A* (p21) in 64% of bladder tumors and found that increased expression was associated with a decreased probability of tumor recurrence and improved patient survival. Decreased *CDKN1B* (p27) expression has also been linked to increasing tumor grade, pathologic stage, and poor survival in bladder carcinoma (Del Pizzo et al, 1999).

The expression of *CDKN1A* in prostate cancer has not shown a clear correlation with advanced disease or poor outcome (Kibel and Isaacs, 2000). However, specific genetic polymorphisms in *CDKN1A* and *CDKN1B* have been associated with advanced disease (Kibel et al, 2003), and altered expression of *CDKN1B* has been implicated in aggressive disease in multiple studies. Cordon-Cardo and colleagues (1998) examined radical prostatectomy specimens and found that absent or low *CDKN1B* production by immunohistochemistry was an independent risk factor for decreased disease-free survival by multivariate analysis. Cote and coworkers (1998) found that decreased *CDKN1B* nuclear staining correlated not only with decreased disease-free survival but also overall survival in patients undergoing radical prostatectomy, whereas Freedland and colleagues (2003) found that patients with *CDKN1B*-positive cells in the prostate needle biopsy specimen had a 2.5-fold increased risk of biochemical recurrence (prostate-specific antigen [PSA] relapse).

The relevance of *CDKN1B* to prostate cancer is also supported by studies of mouse models. For example, mice deficient in *CDKN1B* develop prostate hyperplasia, confirming the potential importance of this gene in prostate tissue homeostasis (Cordon-Cardo et al, 1998). Other studies have shown that mice deficient in both *CDKN1B* and *PTEN* have a high incidence of prostate cancer (Di Cristofano et al, 2001).

TP53 Tumor Suppressor

The TP53 tumor suppressor protein is a key player in cell cycle checkpoints, responding to DNA damage by signaling cell cycle arrest and repair of the damage (Fig. 19-9). If the DNA damage cannot be repaired, TP53 may trigger cell death (apoptosis). TP53 is the most commonly mutated gene in cancer and plays a prominent role in GU malignancies. Alterations to TP53 in regard to GU cancers are discussed in detail in the following sections.

Figure 19-9. TP53 plays a central role in the cell's response to extra-cellular stimuli. Radiation, hypoxia, redox reactions, and oncogenes all can increase TP53 activity through different mechanisms. In response, the cell initially stops dividing and then attempts to repair the DNA damage. If it fails to repair the DNA, it undergoes apoptosis (programmed cell death). These functions are mediated through transcriptional activation of various genes, some examples of which are indicated in the figure.

KEY POINTS: CELL CYCLE Deregulation

- The cell cycle consists of an ordered, unidirectional series of events, the main goal of which is to replicate the cell's genome and partition one copy into each of two resulting daughter cells.
- The cell cycle is divided into four phases; G₁, S, G₂, and M. The transition from G₁ into S phase is critically dependent on phosphorylation of the RB1 tumor suppressor protein. Mutations in *RB1* are common in urologic malignancies.
- Phase-specific phosphorylation of substrate proteins by cdks orchestrates progression through the cycle.
- The activities of cdks depend on their association with specific cyclin proteins. Cyclins accumulate and are rapidly degraded in a phase-specific manner, ensuring the proper sequencing and irreversibility of key events throughout the cell cycle.
- Primary points of cell cycle control are the G₁/S and G₂/M checkpoints. Checkpoints employ CDKIs to pause the cell cycle in response to various signals, including DNA damage, cell-cell contact, cytokine release, and hypoxia.
- The TP53 tumor suppressor protein is a key player in cell cycle checkpoints, responding to DNA damage by signaling cell cycle arrest and repair of the DNA damage. If the DNA damage cannot be repaired, TP53 may trigger cell death (apoptosis).
- TP53 is the most commonly mutated gene in cancer and plays a prominent role in GU malignancies.
- Defects in cell cycle checkpoints lead to unregulated cell proliferation and genetic instability.

DNA METHYLATION

The covalent modification of the C-5 position of cytosine by a methyl group is mediated by DNA methyltransferase, resulting in the formation of 5-methylcytosine, an epigenetic modification of DNA that occurs in vertebrates and is essential for normal embryonic development (Jones, 1986; Bird, 1992). Methylation of cytosine occurs primarily at the CpG palindrome in DNA. The presence of 5-methylcytosine at CpG dinucleotides has resulted in a significant depletion of this sequence from the genome during the course

of vertebrate evolution (Schorderet and Gartler, 1992). This reduction in frequency of CpG dinucleotides in the genome is the result of spontaneous deamination of 5-methylcytosine to thymine (Rideout et al, 1990; Sved and Bird, 1990). Certain areas of the genome do not show a depletion of the CpG dinucleotides and contain the expected frequency of this sequence. These regions are referred to as CpG islands; although CpG islands constitute approximately 1% of vertebrate genomes, they account for approximately 15% of the total number of CpG dinucleotides in DNA (Bird, 1986; Gardiner-Garden and Frommer, 1987). CpG islands are typically located upstream of many ubiquitous housekeeping and tissue-specific genes. CpG island methylation affects the levels of gene transcription (Cedar, 1988). Hypermethylation of CpG islands usually results in transcriptional downregulation, whereas hypomethylation of these regions may increase gene expression.

CpG islands located in the promoter regions of tumor suppressor genes are normally unmethylated. Abnormal methylation of these regions may result in a progressive reduction in gene expression, altering normal cellular growth control in favor of proliferation. Methylation of CpG islands may lead to decreased gene expression by mechanisms including changes in local chromatin structure, inhibition of transcription factor binding, or exclusion of transcriptional machinery from methylated promoter DNA (Bird and Wolffe, 1999). The epigenetic properties of methylation may affect gene activity without altering the DNA sequence and represent an alternative means of gene inactivation apart from gene mutation or deletion.

Changes in global levels and regional patterns of DNA methylation are among the earliest and most frequent events known to occur in human cancer (Jones and Baylin, 2002). Alterations in DNA methylation have a direct impact on mutational and epigenetic components that may contribute to neoplastic transformation. Three major pathways by which DNA methylation may result in genetic dysregulation in human cancer include (1) inherent mutational effects of 5-methylcytosine, (2) epigenetic effects of promoter methylation on gene transcription, and (3) potential gene activation and induction of chromosomal instability by DNA hypomethylation (Gonzalzo and Jones, 1997; Jones and Gonzalzo, 1997).

DNA Methylation and Prostate Cancer

Glutathione-S-transferases belong to a superfamily of enzymes responsible for detoxification of a wide range of xenobiotics. These enzymes catalyze the nucleophilic attack of reduced glutathione on potentially damaging electrophilic compounds. **Aberrant methylation of the CpG island at the glutathione-S-transferase pi (*GSTP1*) locus is the most frequent somatic genome alteration reported in prostate cancer** (Lee et al, 1994; Jerónimo et al, 2001). Methylation of *GSTP1* has been detected in greater than 90% of prostate carcinomas and approximately 70% of prostatic intraepithelial neoplasia (PIN) lesions, but it is not present in normal prostate tissue or benign prostatic hyperplasia (Lee et al, 1994). In normal prostate tissue, expression of *GSTP1* is limited to basal cells, but it can be upregulated in columnar epithelial cells exposed to oxidative stress. Increased levels of DNA methylation have also been associated with worse clinical outcomes in patients with prostate cancer (Maruyama et al, 2002).

The ras association domain family protein 1 isoform A (*RASSF1A*) gene is located on chromosome 3p21. *RASSF1A* is a tumor suppressor gene that is frequently altered in various human cancers. Abnormal methylation of *RASSF1A* has been reported to occur in 60% to 70% of prostate carcinomas (Kuzmin et al, 2002). Loss of heterozygosity (LOH) of the 3p21 region is associated with methylation and silencing of the remaining *RASSF1A* allele during tumorigenesis. Methylation *RASSF1A* has been observed more frequently in higher grade prostate cancers compared with less aggressive tumors (Liu et al, 2002).

Genome-wide methylation analyses were conducted in prostate cancer more recently, and the results indicated that there are widespread changes in methylation patterns (both hypermethylation

and hypomethylation) that occur in both gene-associated and conserved intergenic regions. Although interindividual heterogeneity in DNA methylation patterns was observed among patients with prostate cancer, in individuals with metastatic prostate cancer, DNA methylation alterations were highly conserved across all of their metastases, suggesting that DNA methylation alterations undergo clonal selection (Yegnasubramanian et al, 2011; Aryee et al, 2013).

Role of DNA Methylation in Bladder Cancer

Mutations of the *TP53* gene are present in more than half of all human malignancies. Many of the mutational hot spots found in the *TP53* gene occur at CpG dinucleotides that are normally methylated, implicating 5-methylcytosine as an endogenous mutagen in the genome (Rideout et al, 1990; Greenblatt et al, 1994; Tornaletti and Pfeifer, 1995). Mutational inactivation of *TP53* is a frequent event in urothelial dysplasia, carcinoma in situ (CIS), and invasive bladder cancer (Spruck et al, 1994).

The contribution of DNA methylation to these mutational events varies depending on the type of bladder cancer and the etiologic agent believed to be responsible for tumor formation (Jones et al, 1998). Urothelial carcinomas in Western countries and Japan have relatively few mutations at CpG sites, suggesting that DNA methylation may not play a major role in inducing these changes. In contrast, a higher frequency of mutations at CpG dinucleotides consistent with 5-methylcytosine deamination is observed in patients with squamous cell carcinoma and urothelial carcinoma with a history of exposure to phenacetin or arsenic (Jones et al, 1998). These observations highlight the potential mutagenic effects of DNA methylation on the genome and the contribution of methylation to *TP53* inactivation during bladder carcinogenesis.

INK4A (p16) Methylation in Bladder Cancer

Inactivation of the *INK4A* gene may occur by various mechanisms, including deletion, mutation, and promoter methylation (Spruck et al, 1994; Gonzalez-Zulueta et al, 1995; Herman et al, 1995). Mutation or deletion of one *INK4A* allele and concurrent methylation of the remaining allele results in complete loss of functional activity. Methylation of *INK4A* has been reported in 27% to 60% of primary urothelial carcinomas (Chan et al, 2002; Chang et al, 2003). Such epigenetic changes are among the earliest molecular events associated with transformation and may precede morphologic alterations in cellular architecture.

The first detailed study investigating the effects of *INK4A* promoter methylation on transcriptional activity was performed in bladder cancer cells, where a reduction in *INK4A* expression was associated with higher levels of methylation in the upstream promoter region. Methylation of specific CpG sites in the *INK4A* promoter was shown to result in significant downregulation of transcriptional activity of the gene (Gonzalzo et al, 1998). Administration of the demethylating agent 5-aza-2'-deoxycytidine (5-Aza-CdR) was capable of reactivating *INK4A* expression in bladder cancer cells that were previously shown to contain methylated alleles of the gene. Methylation in exon 2 of the *INK4A* gene is also a frequent occurrence in various cancers and is an excellent marker for transformation, although the presence of methylation in this region of the *INK4A* gene does not affect *INK4A* transcription in bladder cancer cells (Gonzalzo et al, 1998).

Hypermethylation of Other Genes in Bladder Cancer

The E-cadherin (*CDH1*) gene encodes a transmembrane glycoprotein that modulates calcium-dependent intercellular adhesion in epithelial tissues. Methylation of the CpG island located in the *CDH1* promoter is associated with decreased gene expression in high-grade urothelial carcinoma, including disease associated with CIS (Graff et al, 1995; Horikawa et al, 2003). *CDH1* methylation has also been reported in histologically normal urothelium; however, many of these cases were from patients older than 70 years of age and may be related to a potential link between

methylation and aging (Ahuja and Issa, 2000; Bornman et al, 2001). Lower levels of CDH1 expression may increase β -catenin/T-cell factor/lymphocyte enhancer factor signaling activity and proliferation in urothelial carcinomas (Maruyama et al, 2002; Thievsen et al, 2003).

Methylation of *RASSF1A* has been reported in 97% of primary bladder tumors, suggesting that epigenetic inactivation of this gene may play an important role in bladder carcinogenesis (Lee et al, 2001). High tumor grade, nonpapillary growth pattern, and muscle-invasive disease are associated with *RASSF1A* promoter methylation in bladder cancer (Maruyama et al, 2001).

Hypomethylation in Bladder Cancer

Global DNA hypomethylation is also a frequent event in tumorigenesis (Jones and Baylin, 2002). Hypomethylation may result in genomic instability via alterations in chromatin structure, increased genetic recombination between repetitive elements, or derepression of retrotransposons (Baylin et al, 2001). Methylation of CpG sites is normally maintained by the enzymatic activities of DNA methyltransferase 1 (*DNMT1*), whereas de novo methylation of CpG sites is mediated by DNA methyltransferases 3A and 3B (*DNMT3A*, *DNMT3B*) (Jones and Baylin, 2002). One important role for methylation is genomic imprinting, which results in monoallelic gene expression without altering the genetic sequence. Loss of imprinting is a reduction in the methylation of the normally methylated allele that can lead to activation of the normally silent copy of a growth-promoting gene (Feinberg and Tycko, 2004). This phenomenon has been reported for the human insulin-like growth factor-2 gene (*IGF2*) in various cancers (Woodson et al, 2004; Sakatani et al, 2005).

Methylation of long interspersed nuclear element (L1 LINE) sequences is reduced in bladder cancer cell lines and primary tumors compared with normal bladder mucosa (Jürgens et al, 1996). However, DNA methyltransferase expression did not correlate with methylation status of cell lines, and methyltransferase activity was reduced in quiescent cells suggesting that aberrant expression of *DNMT1* does not account for the altered methylation patterns found in urothelial carcinoma (Jürgens et al, 1996). Decreased *DNMT1* expression and induction of *DNMT3A* and *DNMT3B* in bladder cancer have also been reported (Kimura et al, 2003). These data suggest that downregulation of *DNMT1* expression may be at least partly responsible for hypomethylation of repetitive elements in bladder cancer.

KEY POINTS: DNA METHYLATION

- Methylation occurs specifically at CpG dinucleotides in the genome. The presence of 5-methylcytosine in DNA can result in spontaneous deamination to thymine and the formation of C→T transition mutations.
- DNA methylation can affect gene function by subsequent mutational events or epigenetic mechanisms. Methylation of CpG islands associated with the promoter region of genes may result in suppression of gene expression.
- Loss of promoter methylation of normally methylated genes can lead to inappropriate gene expression (e.g., expression of oncogenes).

DNA DAMAGE AND REPAIR

Cancer is fundamentally a genetic disease. Alterations in numerous genes provide the malignant cell the means to activate cancer-associated pathways and inactivate tumor suppressive barriers, making possible the acquisition of the key set of attributes associated with the cancer phenotype. The intrinsic accuracy of DNA polymerase coupled with associated error-correction mechanisms keeps the error rate during DNA replication to an astonishingly low estimated value of approximately three incorrect

bases per cell division—in a genome of more than 3 billion bases! However, these processes are not perfect, and cancer-causing changes occur in oncogenes and tumor suppressor genes via epigenetic, mutational, and copy number alterations (CNAs), in addition to epigenetic abnormalities. Many of these genetic changes are thought to result from various endogenous (e.g., mitochondrial respiratory by-products) and exogenous (e.g., chemicals, radiation) DNA-damaging agents that constantly assault the genome (Ames and Gold, 1991, 1998). To counter these threats, cells employ a plethora of defensive mechanisms, including free radical scavengers such as α -tocopherol, vitamin C, carotenoids, bilirubin, and urate as well as protective enzymes such as superoxide dismutases, glutathione peroxidases, and glutathione transferases, which serve to detoxify a wide range of carcinogens (Mates and Sanchez-Jimenez, 1999; Finkel and Holbrook, 2000). Loss of expression, owing to promoter hypermethylation, of the glutathione-S-transferase pi enzyme encoded by the *GSTP1* gene is observed in most prostate cancer cases (Lee et al, 1994; Lin et al, 2001), and more recent studies have found associations between genetic polymorphisms in glutathione-S-transferases and the risk of biochemical recurrence in patients with prostate cancer (Nock et al, 2009). Epidemiologic and retrospective studies on prostate cancer risk have found a protective effect for selenium, which is used as a cofactor by glutathione peroxidases (Lowe and Frazee, 2006; Colli and Amling, 2009), raising hope that dietary intervention might be protective against prostate cancer. However, a large clinical trial showed no benefit for dietary supplementation with selenium (Hatfield and Gladyshev, 2009), and it now appears that observed protective effects of selenium may be limited to men with low baseline selenium levels. Results from other clinical chemoprevention trials in prostate cancer have been similarly disappointing (Gaziano et al, 2009).

In addition to DNA damage prevention, the cell employs a host of DNA repair systems. The set of pathways dealing with DNA damage recognition and repair is referred to as the DNA damage response (DDR) and encompasses a plethora of genes. The DDR includes the replication machinery itself (with its associated proof-reading capability) and the many components of specific DNA repair systems, such as base excision repair, nucleotide excision repair, double-stranded break repair, and mismatch repair described in detail further on (Loeb, 1998; Schmutte and Fishel, 1999).

As previously mentioned, the cell cycle and the DDR are closely integrated. In response to DNA damage, the first step is to arrest the cell cycle so that the DNA can be repaired. There is substantial overlap between the initiators of DNA repair and cell cycle arrest (Kastan and Bartek, 2004). For example, ATM and ATR kinases are both activated in response to DNA damage, and both activate TP53, CHK1, and other proteins critical to cell cycle arrest (Bartek and Lukas, 2003).

Considering the number of genetic changes calculated to be required for cancer development as well as the large number of changes actually observed in cancer cells and taking into account the very low spontaneous mutation rates in normal human cells, Loeb concluded that the spontaneous mutation rate is insufficient to explain the number of mutations observed in most human cancers. Loeb hypothesized that early in the process of tumorigenesis, preneoplastic cells might develop defects in one or more of the genes responsible for the fidelity of DNA replication (Loeb et al, 1974; Loeb, 1991; Cheng and Loeb, 1993). Such a defect would lead to an increased mutation rate resulting in a so-called mutator phenotype. This hypothesis gains further support from the fact that most cells in proliferating tissues, such as epithelial tissues, the source of most human cancers, are relatively short-lived, being eliminated either by cell shedding or by apoptosis. The target population of cells at risk for becoming cancerous is far less than the total number of cells in the body, yet cancers are common. In addition, cells with a “hypermutable” phenotype are often more difficult to treat because the selection pressure of therapy may rapidly select tumor cells with mutations conferring resistance (Tlsty et al, 1989).

The term *mutator phenotype* was originally used to refer to defects in the DNA replication and repair proteins, resulting in

small-scale errors in the DNA sequence, such as single base substitutions, deletions, and duplications. Despite (or perhaps because of) the many potential targets for mutator genes, few such genes have been found to be consistently mutated in significant proportions of common human cancers, a notable exception being the mismatch repair pathway. Mismatch repair defects are the underlying cause of hereditary nonpolyposis colorectal cancer (Aaltonen et al, 1993) and have been reported in 15% of sporadic colon cancers (Liu et al, 1995).

Although defects in DNA repair genes in sporadic malignancies, including GU tumors, have been identified, Loeb's concept of the mutator phenotype, as originally stated, has yet to be fully evaluated, and it currently appears that it may not be a major player in the development of most common sporadic human cancers. However, if one broadens the mutator concept to include systems involved in *chromosomal stability*, it may become widely applicable. At any rate, the current consensus is that *genetic instability of some sort is required for cancer development*.

Additional information on DNA repair mechanisms (nucleotide excision repair, base excision repair, mismatch repair, DNA double-stranded break repair, nonhomologous end joining) can be found on the Expert Consult website.

KEY POINTS: DNA DAMAGE AND REPAIR

- DNA damage does not often lead to malignancy because the cell possesses multiple repair mechanisms.
- Defects in DNA repair facilitate the accumulation of the mutations critical for tumor formation and progression.
- NER is a major defense against DNA damage caused by ultraviolet radiation and chemical exposure.
- BER repairs DNA damage caused by spontaneous deamination of bases, radiation, oxidative stress, alkylating agents, and replication errors.
- MMR removes nucleotides mispaired by DNA polymerase.
- Double-stranded break repair is a major defense against DNA damage caused by ionizing radiation, free radicals, and chemicals.
- Many syndromes that involve inherited defects in DNA repair exhibit marked increases in cancer susceptibility, strongly linking genomic instability and cancer.

GENOMIC ALTERATIONS

Although the ultimate source of genetic instability in cancer is still unclear, research by many different groups on several different tumor types has strongly implicated genetic instability as an important determinant of tumorigenesis (Loeb, 1991; Hartwell, 1992). As mentioned previously, although important in specific instances, such as inherited cancer susceptibility syndromes, deficiencies in genes involved in the replication, maintenance, and repair of DNA have not yet been shown to play a major direct role in the genesis of most sporadic human cancers. More recent studies on numerous human cancers found that the genomes of each cancer have numerous mutations (on average 33 to 66 somatic mutations in solid tumors) in gene coding sequences that are predicted to alter significantly the corresponding protein products (Vogelstein et al, 2013). Comprehensive sequencing efforts coupled with statistical methods to predict the effects of individual mutations have revealed that approximately 140 genes, when mutated, can “drive” tumorigenesis (e.g., “driver” genes). Most tumors contain only two to eight such driver mutations, whereas the remaining mutations in any particular cancer case are considered “passengers” that do not confer a selective growth advantage (Sjoberg et al, 2006; Wood et al, 2007; Vogelstein et al, 2013).

Apart from the sequence alterations predicted to arise from the original mutator phenotype concept, *chromosomal* instability leads

to gross changes in chromosome number and structure or both. The spectrum and severity of such chromosomal alterations may differ for different tumor types. For instance, **hematologic malignancies often manifest with simple diploid or near-diploid karyotypes with only one or very few detectable, often balanced, chromosomal rearrangements**. However, as a class, these cancers account for only about 10% of all human cancers. **In stark contrast, the presence of large variations in chromosome numbers and complex structural rearrangements as well as intratumoral variation in these aberrations are hallmarks of most human solid tumors**, which represent the bulk of human malignancies. Important exceptions include certain tumors deficient in MMR. **In prostate cancer as well as most human tumor types and transplantable tumor models, the extent of chromosomal abnormalities correlates with disease severity and aggressiveness**, pointing to a role for these changes in cancer progression—spanning from premalignant lesions to localized primary tumors to metastatic disease to which patients typically succumb (Brothman et al, 1990; Lundgren et al, 1992; Sandberg, 1992; Isaacs et al, 1995; Bostwick et al, 1996). For example, in a study that used a computational method to infer aneuploidy based on gene expression data of genes that are located in adjacent chromosomal regions, greater levels of aneuploidy were found to confer worse survival (Carter et al, 2006). Likewise, a study on prostate cancer performed unsupervised hierarchical clustering of copy number alterations (CNAs) in 218 tumor samples and found that tumors with the highest number of genome-wide CNAs had a significantly accelerated time to biochemical recurrence (Taylor et al, 2010).

The chromosomal changes seen in solid tumors can be broken down into two main classes: **changes in the number of whole chromosomes and changes in chromosomal structure**. Numerical chromosomal alterations can be subdivided further into changes in the numbers of specific individual chromosomes, aneusomies (e.g., monosomies and trisomies), and changes in the number of copies of the entire diploid set of chromosomes, ploidy changes (e.g., tetraploidy, octaploidy). Possible mechanisms responsible for such numerical changes include nondisjunction, endoreduplication (an abrupt doubling of the chromosome complement without cell division), cytokinesis defects, and cell fusion events. Likewise, structural changes can be subdivided into several distinct types of chromosomal aberrations as listed in Box 19-2. An additional mechanism

BOX 19-2 Gross Chromosomal Abnormalities Frequently Observed in Cancer

NUMERICAL ABNORMALITIES

- Aneuploidies
- Abnormal numbers of whole chromosome complement (e.g., triploidy, tetraploidy)
- Losses or gains of single chromosomes (e.g., monosomy, trisomy)

STRUCTURAL ABNORMALITIES

- Rearrangements
- Inversions
- Translocations (either balanced or unbalanced)
- Chromothripsis
- Chromosomal fusions
- End-to-end fusion = dicentric chromosome
- Intrachromosomal fusion = ring chromosome
- Deletions (from small segments up to entire chromosome arms)
- Duplications, amplifications
- Double minutes (often containing amplified sequences)
- Isochromosomes (loss of one chromosomal arm, replaced by duplication of the remaining arm)
- Complex (various combinations of the above-listed abnormalities)

DNA Repair Mechanisms

It has been estimated that each cell's genome experiences on the order of 10,000 lesions per day from reactions with oxidative species alone (Ames et al, 1993). Other processes, such as spontaneous loss of individual DNA bases (depurination and depyrimidination) and spontaneous deamination of bases, also occur at appreciable rates. In addition to damage prevention, the cell employs a host of DNA repair systems (Fig. 19-10). The relevance of DNA maintenance pathways to human cancer is borne out by the fact that many recessively inherited cancer predisposition syndromes (e.g., xeroderma pigmentosum, Bloom syndrome, Werner syndrome, ataxia telangiectasia, hereditary breast and colon cancer syndromes) are caused by defects in genes involved with DNA maintenance and repair, strongly implicating hypermutability in cancer causation (Modrich, 1994; Sancar et al, 1996; Patel et al, 1998). Three repair systems exist to deal with damage at the level of the DNA bases themselves. Such damage includes base modifications arising from reactive chemical species and from base mismatches secondary to rare misincorporation of incorrect bases or chemical conversions. The first of these, nucleotide excision repair (NER), is a major defense against DNA damage caused by ultraviolet radiation and chemical exposure. NER acts on a wide range of alterations that result in large local distortions in DNA, by recognizing distortions in the DNA helix, excising the damaged DNA, and replacing it with the correct sequence (Wood, 1997).

In base excision repair (BER), damage caused by various events, including spontaneous deamination of bases, radiation, oxidative stress, alkylating agents, or replication errors, is corrected. In particular, the pathway is critical for repair of oxidative lesions caused by reactive oxygen species. In contrast to NER, lesions recognized by BER do not tend to create major distortions in the DNA molecule.

In human cancers, mutations in the MUTYH glycosylase, a component of BER that removes damaged bases, are associated with colorectal carcinoma. This glycosylase functions with another glycosylase, OGG1, to correct A/G and A/C mismatches (Al-Tassan

et al, 2002). Polymorphic variants of OGG1 have been implicated in GU malignancies, including prostate cancer (Xu et al, 2002b). Mismatch repair (MMR) removes nucleotides mispaired by DNA polymerases and insertion/deletion loops (ranging from 1 to 10 or more bases) that result from slippage during replication of repetitive sequences or during recombination. The MMR pathway functions primarily to reverse incorporation errors made by DNA polymerase. Defects in MMR compromise DNA replication fidelity by approximately 2 orders of magnitude, dramatically increasing mutation rates. Genetic inactivation of MMR genes, particularly *MLH1*, is a frequent event in sporadic colon carcinoma (Veigl et al, 1998) and has been implicated in prostate (Boyer et al, 1995) and bladder (Christensen et al, 1998) carcinomas. The finding that MMR knockout mice are cancer prone provides additional evidence that defects in MMR repair can contribute substantially to tumorigenesis (Friedberg et al, 1998).

Double-Stranded Break Repair

DNA double-strand breaks (DSBs) arise from various causes, including ionizing radiation or radiographs, free radicals, and reactive chemical species as well as during replication of DNA containing single-strand breaks. After DSB detection, a complex cascade of reactions is triggered that halts the cell cycle and recruits specific repair factors (Kastan and Bartek, 2004). DSBs have the potential to be the most disruptive form of DNA damage. If they are not repaired, the cell often undergoes apoptosis. This apoptotic response to DNA DSBs is the basis of radiation therapy and many chemotherapeutic agents that function primarily by inducing DSBs. Cancer cells that have abrogated this response may exhibit increased resistance to such therapies. Incorrectly repaired DNA can lead to DNA mutations, deletions, and structural chromosomal rearrangements that are nearly ubiquitous in human solid tumors. There are two DSB repair pathways: homologous recombination (HR) and nonhomologous end joining (NHEJ) (Sancar et al, 2004).

The ATM kinase is a key player in DSB repair (Berkovich et al, 2007). By mechanisms that are still unclear, DSBs are quickly

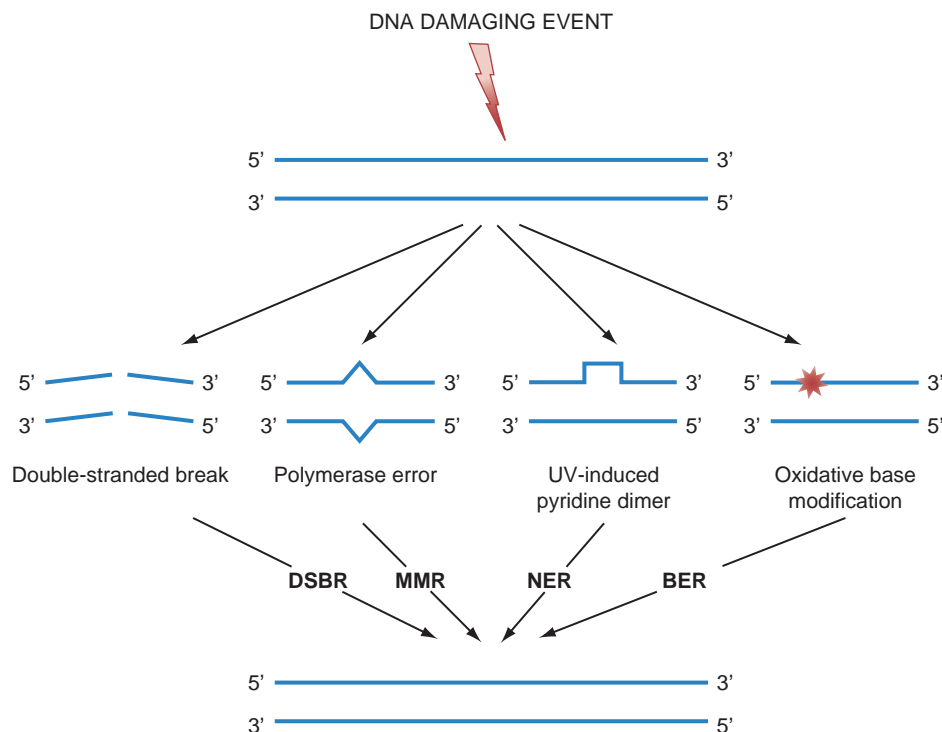

Figure 19-10. Schematic drawing of different DNA damaging events and repair mechanisms. BER, base excision repair; DSBR, double-stranded break repair; MMR, mismatch repair; NER, nucleotide excision repair.

recognized, leading to rapid ATM activation via phosphorylation. Activated ATM phosphorylates and activates TP53 and kinases CHECK1 and CHECK2, which, among other things, act to halt cell cycle progression to allow for DNA repair (Fig. 19-11 on the Expert Consult website). ATM also activates many proteins involved in

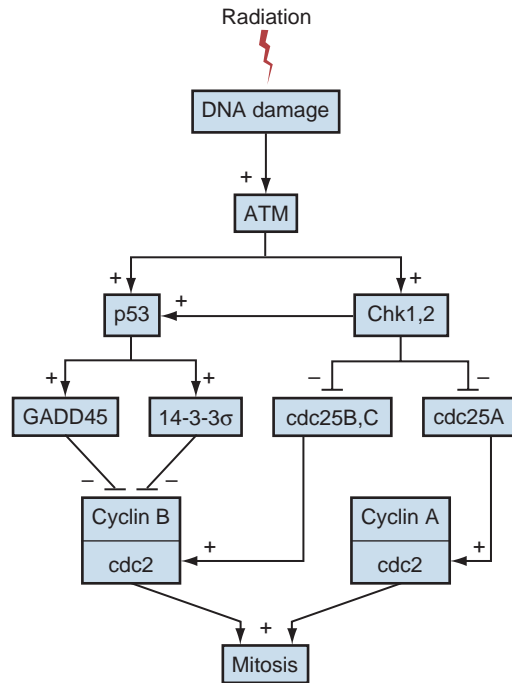

Figure 19-11. Schematic representation of the cascade at the G₂/M checkpoint in response to genotoxic events such as radiation. Increased ATM kinase activity eventually leads to inhibition of cyclin B through p53 and decreased stimulation of Cdc2 through Chk1 and Chk2; this leads to cell cycle arrest.

DSB repair, such as the histone H2A variant H2AX (Rogakou et al, 1998; Lukas et al, 2003), NBS1, BRCA1, and SMC1 (Kitagawa et al, 2004). Phosphorylated H2AX (also known as gamma H2AX) binds at the breakpoint and occupies a sizeable stretch of DNA (up to 30 Mbp) on either side of the break where it serves to recruit other DDR factors creating so-called repair foci (Rogakou et al, 1999; Bassal and El-Osta, 2005). Activated NBS1-MRE11-RAD50 (MRN) complex can then bind to Rad52 and the broken chromosomal ends (Lobachev et al, 2004). RAD51 along with the breast cancer susceptibility gene products, BRCA1 and BRCA2, plus the BRCA1-associated-RING-domain 1 protein (BARD1) participate in replicating the undamaged region from the sister chromosome template (Welch et al, 2000; Sancar et al, 2004). Homologous recombination involves the transfer of genetic information between sister chromatids. Essentially, homologous repair allows the normal undamaged sister chromatid to act as a template to allow precise repair of a damaged segment of DNA (Johnson et al, 1999). Use of the sister chromatid is only an option following S phase into G₂, before mitosis has occurred.

NHEJ is the more extreme of the two DSB repair pathways. In this instance, broken ends are brought together and ligated, often with a loss of some nucleotides at the resulting joint. In addition, the potential exists for incorrectly joining broken DNA ends that were not originally juxtaposed in the genome, creating chromosomal rearrangements such as chromosomal translocations. The Ku protein is a heterodimer consisting of XRCC6 (Ku70) and XRCC5 (Ku80) subunits that initiates NHEJ by binding to the broken ends of the DNA (Tuteja and Tuteja, 2000). Ku complexes with DNA-dependent protein kinase PRKDC (DNA-PK catalytic subunit) and in doing so activates kinase activity of PRKDC (Anderson, 1993). Active PRKDC phosphorylates numerous proteins involved in the repair process, including Ku and H2AX. Phosphorylated Ku uses its helicase activity to unwind the damaged DNA and allows the ligase 4/Xrcc4 heterodimer to repair the break (Tuteja and Tuteja, 2000).

Similar to other DNA repair mechanisms, defects in DSB repair have been linked to cancer. BRCA1 and BRCA2 are associated with familial breast and ovarian cancer (Miki et al, 1994; Wooster et al, 1995). Such inherited cancer predisposition syndromes further highlight the existing link between genomic instability and cancer causation.

for genomic rearrangement, termed *chromothripsis* (literally meaning “chromosome shattering”), has been described that was initially extrapolated from genomic sequencing studies on cancer cells (Stephens et al, 2011). Chromothripsis is evidenced by a large number (possibly hundreds) of chromosomal rearrangements in confined chromosomal regions that have occurred after apparent shattering and rejoining of a chromosomal region in a sometimes disordered fashion.

As previously mentioned, cancer-associated chromosomal changes were recognized in the 1900s by Boveri, who proposed that such abnormalities might be involved in cancer causation. Much later, Klein (1981) suggested that chromosomal rearrangements affect the expression of cancer-related genes located near the observed chromosomal breakpoints. This hypothesis has been validated over the ensuing years, in large part as a result of studies on what were observed to be consistent chromosomal changes found in hematologic malignancies and soft tissue sarcomas, eventually leading to the isolation and cloning of the resident genes involved (Nowell, 1994). Over the years, painstaking dissection of chromosomal regions that are repeatedly found to undergo alteration in specific tumor types or subtypes has led to the discovery of hundreds of individual cancer-associated genes. Typically, genomic loci that are frequently lost tend to harbor tumor suppressor genes, whereas loci exhibiting copy number gains (e.g., gene amplification) point toward oncogenes (Snijders et al, 2005). Examples of genes frequently amplified in cancers include members of the *MYC*, *RAS*, *EGFR*, and *FGF* gene families as well as cell cycle regulatory genes such as *CCND1* (cyclin D gene), *CDK4*, and *HDM2*. Gene amplifications in cancer are usually seen either as multiple small extrachromosomal copies, called *double minutes*, or as amplified regions within chromosomes, so-called homogeneous staining regions (Cowell, 1982).

Specific Chromosomal Rearrangements in Genitourinary Malignancies

Recurrent Gene Rearrangements in Prostate Cancer

Although they are much less frequently observed in common adult solid tumors, recurrent translocations do occur, often amid the backdrop of countless chromosomal abnormalities (Sandberg, 1985). One of the most exciting more recent findings in prostate cancer research has been the discovery of recurrent structural rearrangements in most prostate cancer cases, primarily involving oncogenic ETS transcription factor family members. The initial report by Tomlins and coworkers in 2005 described the use of a novel bioinformatic approach that led to the identification of recurrent gene fusions between the upstream regulatory region of the androgen-regulated gene *TMPRSS2* and *ERG*, an ETS family member previously known to be involved in Ewing sarcoma and various leukemias. These two genes reside 3 Mb apart on chromosome 21 (*TMPRSS2*, 21q22.3; *ERG*, 21q22.2), and detailed molecular analysis revealed that in most rearranged cases (approximately two thirds), the gene fusion occurs via deletion of the intervening sequence, with the remaining fusions resulting from more complex, translocation-type rearrangements (Tomlins et al, 2005; Perner et al, 2007). In either case, the net result is to place a known oncogenic transcription factor under the control of an androgen-regulated promoter, resulting in androgen-driven expression of the fusion transcript (Wang et al, 2008a). As expected, increased *ERG* transcription and *ERG* protein expression are positively correlated with presence of the gene fusion. In addition to various splice variants, there are multiple forms of the genomic rearrangement, the most common one being a fusion between exon 1 of *TMPRSS2* and exon 4 of *ERG*. These gene rearrangements can be readily detected, either by assaying for the presence of the fusion transcripts by reverse-transcription polymerase chain reaction (PCR) or by assaying for the rearrangement directly by multiprobe, multicolor fluorescence in situ hybridization (FISH). Such approaches are currently being evaluated for potential use in noninvasive diagnostic applications (e.g., in urine or blood).

More recently, detection of *ERG* protein expression by immunostaining has been shown to be an excellent surrogate marker for chromosomal rearrangements involving the *ERG* gene, providing a simpler method for their detection (Park et al, 2010; Chaux et al, 2011; Falzarano et al, 2011).

Since the publication of the initial report by Tomlins and coworkers, several large retrospective studies have been performed assessing these fusions in localized prostate cancers in PSA-screened cohorts. These studies confirmed the initial finding and found the prevalence of the *TMPRSS2-ERG* fusion in prostate cancer to be 40% to 60%, making this one of the most common somatic genetic alterations in prostate cancer (Mehra et al, 2007; Nam et al, 2007; Perner et al, 2007; Tu et al, 2007; Wang et al, 2008a; Gopalan et al, 2009b; Mosquera et al, 2009). One anatomic exception is cancer originating in the transition zone of the prostate, which appears to lack *TMPRSS2-ERG* gene rearrangements completely (Guo et al, 2009a).

As assessed by FISH in tissue sections, the *TMPRSS2-ERG* fusion has not been observed in benign prostate epithelial or stromal cells, although it has been reported to be present in high-grade prostatic intraepithelial neoplasia (PIN), the presumptive precursor lesion for prostate adenocarcinoma, at frequencies between 15% and 20%, which is about one half the frequency observed in localized PSA-detected cancers (Cerveira et al, 2006; Perner et al, 2007; Mosquera et al, 2008; Han et al, 2009). This finding implies that, at least in a subset of cases, the rearrangement may be an early event in prostate tumorigenesis. With the important exceptions of transition zone cancers and high-grade PIN, the prevalence and high degree of specificity of the *TMPRSS2-ERG* fusion for prostate cancer makes this a potentially useful biomarker for diagnosis and disease monitoring, one that could be used in conjunction with current markers such as serum PSA that have limited specificity. The detection of *TMPRSS2-ERG* fusion-driven *ERG* overexpression in prostate biopsy specimens from men found to have only high-grade PIN was shown to be predictive of cancer diagnosis on subsequent biopsy (Park et al, 2014), and multiple studies have demonstrated the utility of *TMPRSS2-ERG* detection in the blood or urine either alone or in combination with the non-protein-coding RNA prostate cancer antigen 3 (PCA3) in enhancing the sensitivity of prostate cancer diagnosis (Hessels et al, 2007; Tomlins et al, 2011; Leyten et al, 2014).

Apart from the promising potential of *TMPRSS2-ERG* as a diagnostic prostate cancer marker, it is unclear at the present time if additional clinical information might be provided by determining a patient's *TMPRSS2-ERG* gene fusion status. The prognostic significance of fusion status in prostate cancer remains uncertain. Although several studies have reported associations between *TMPRSS2-ERG* rearrangement and various indicators of disease aggressiveness, including higher stage, presence of metastases, and disease-specific death (Demichelis et al, 2007; Mehra et al, 2007; Nam et al, 2007; Perner et al, 2007; Rajput et al, 2007; Attard et al, 2008a; Cheville et al, 2008; Barwick et al, 2010; Leyten et al, 2014), several other published studies failed to observe such associations (Yoshimoto et al, 2006; Lapointe et al, 2007; Tu et al, 2007; Dai et al, 2008; Rouzier et al, 2008; Albadine et al, 2009; Darnel et al, 2009; Gopalan et al, 2009b; Lotan et al, 2009; Fine et al, 2010). A large prospective study of 1180 men treated by radical prostatectomy found that the presence of the *TMPRSS2-ERG* rearrangement was not predictive of recurrence or mortality but was associated with tumor stage (Pettersson et al, 2012). Studies examining the prognostic capabilities of *TMPRSS2-ERG* positivity in predicting treatment outcomes to androgen deprivation (Leinonen et al, 2010), abiraterone (Danila et al, 2011), or radiotherapy (Dal Pra et al, 2013) showed no association. In addition, one study reported a link between gene fusion and favorable prognosis (Saramaki et al, 2008), and Petrovics and colleagues (2005) reported that higher levels of *ERG* mRNA expression appeared to be positively associated with disease-free survival. Another study reported that *ERG* gene copy number gain without the presence of the gene fusion is prognostic for recurrence after radical prostatectomy (Toubaji et al, 2011). The precise reasons for these conflicting results are not

apparent. Numerous variables differ among many of these studies, including the nature of the study cohort, sample size, method of cancer detection, how the tissues were obtained, intratumoral heterogeneity in the presence of the fusion (Minner et al, 2013), how the gene fusions were detected (e.g., PCR or FISH), length of patient follow-up, and the clinical end points assessed. Further research in this area is warranted for better resolution of these issues.

Following the report of *TMPRSS2-ERG* rearrangements, further study revealed additional gene fusions in prostate cancer. The *TMPRSS2* gene can fuse to other ETS family member genes including *ETV1*, *ETV4*, and *ETV5* (Tomlins et al, 2005, 2006; Helgeson et al, 2008). These additional translocations are much rarer than the *TMPRSS2-ERG* rearrangement, which is estimated to represent greater than 90% of all fusions involving ETS genes in prostate cancer (Kumar-Sinha et al, 2008). In addition, fusions involving upstream fusion partners other than *TMPRSS2* have been found, including the fusions *SLC45A3-ETV5*, *SLC45A3-ERG*, *HNRPA2B1-ETV5*, and *SLC45A3-ELK4*; however, these are also relatively rare (Tomlins et al, 2007; Attard et al, 2008a, 2008b; Hermans et al, 2008; Maher et al, 2009; Rickman et al, 2009). Although the fusion events in prostate cancer are typically driven by genomic rearrangements, the *SLC45A3-ELK4* fusion was later found to be due to RNA cis-splicing events between these two genes (which are located adjacent to each other on chromosome 1 band q32) with no alterations to the DNA sequence (Zhang et al, 2012). To date, additional low-frequency gene fusions have been identified in prostate cancer that involve non-ETS family members, such as *CDKN1A*, *CD9*, *IKBK4*, the oncogene *PIGU*, the tumor suppressor *RSRC2*, and members of the RAF pathway (*BRAF*, *RAF1*) (Palanisamy et al, 2010; Pflueger et al, 2011; Ren et al, 2012). These studies have been facilitated by next-generation RNA sequencing (RNA-seq or whole “transcriptome” shotgun sequencing) technologies that unbiasedly sequence all RNA species in a sample, with an analysis that is not limited to “annotated” sequences. The results of RNA-seq studies indicate that some of the fusion events that occur in prostate cancer may be “private events” (e.g., occurring in only one patient), implying that the frequency and range of fusion events in prostate cancer may be far greater than what is currently understood (Pflueger et al, 2011).

Recurrent Gene Rearrangements in Renal Cancer

A novel subtype of RCC, MiTF/TFE family translocation carcinomas, has been described that features chromosomal translocations involving one of two members of the microphthalmia transcription factor (MiTF) family (Hemesath et al, 1994; Argani and Ladanyi, 2005). The first involves the *TFE3* gene on chromosome Xp11.2, which translocates to one of several partner genes including *PRCC* (1q21), *ASPL* (17q25), *PSF* (1p34), *NonO* (Xq12; rearranged via inversion), and an unknown gene at 3q12 (Sidhar et al, 1996; Weterman et al, 1996; Argani et al, 2001a, 2001b; Argani and Ladanyi, 2005; Argani et al, 2005; Martignoni et al, 2009). These translocations place the *TFE3* gene under the control of strong promoters that then drive inappropriate expression of *TFE3* (or a *TFE3*-containing fusion protein). In these cancers, *TFE3* protein is readily detectable in the nucleus by IHC staining with anti-*TFE3* antibody, aiding in diagnosis. *TFE3* RCCs are primarily found in children and adolescents and account for most pediatric cases of RCC (Argani and Ladanyi, 2005). Activation of the *MET* proto-oncogene may play a role with *TFE3* in these tumors (Tsuda et al, 2007), which is of interest because these tumors display papillary histologic architecture, and mutations in the *MET* gene are the underlying cause of hereditary papillary RCC (Jeffers et al, 1997).

A second class of MiTF/TFE family translocation carcinomas contains a specific translocation between the *TFEB* gene on 6p21 and the *ALPHA* gene on 11q12 (Argani et al, 2005). Similar to the Xp11 translocation RCCs, this entity is also most commonly found in children and adolescents and shares many other features with the *TFE3* translocation tumors. In addition to IHC staining for *TFE3* and *TFEB* proteins, it was demonstrated that these tumors are also marked by staining for the protein cathepsin K, a shared transcriptional target gene of these transcription factors (Martignoni et al,

2009). The use of such markers or PCR to detect these specific gene fusions may have clinical importance because, as the cathepsin K example shows, these tumors likely are controlled by a different transcriptional program than conventional RCC, and therapeutic targets used against these cancers may not be effective against translocation RCCs.

Recurrent Gene Rearrangements in Testicular Cancer

In testicular germ cell tumors (TGCTs), gain of the short arm of chromosome 12 is a nearly universal finding, with the notable exception of the rare spermatocytic seminoma subtype (Atkin and Baker, 1982; Rodriguez et al, 1993; Rosenberg et al, 1998; Verdorfer et al, 2004). In most cases (approximately 80%), this finding occurs through a structural rearrangement producing an isochromosome 12p—that is, a version of chromosome 12 consisting of 2 p arms and no q (long) arm. In the remaining cases, 12p material is gained through more complex chromosomal rearrangements (Rosenberg et al, 2000; Ottesen et al, 2003; Looijenga et al, 2007). More detailed analyses have revealed amplification of specific regions on 12p, including the area 12p11.2–12p13. One common region of amplification at 12p11.2–12p12.1 contains 22 potential genes, including *KRAS*, a promising candidate TGCT gene, which also undergoes activating mutations in TGCTs (Moul et al, 1992; Olie et al, 1995; Rodriguez et al, 2003; Zafarana et al, 2003; Goddard et al, 2007). An additional region of interest lies at 12p13.31, where the so-called stem cell cluster region is located. This region contains several stem cell–related genes including *CD9*, *EDR1*, *GDF3*, *SCNN1A*, *NANOG*, and *STELLAR*, which exhibit coordinate overexpression (Clark et al, 2004; Korkola et al, 2006).

Other Genomic Alterations in Genitourinary Malignancies

Apart from chromosomal translocations, which are primarily specific changes in the spatial organization of the genome, an overall derangement of the chromosomal complement is nearly universal in human cancer, particularly in carcinomas—cancers that originate from epithelial cells and represent most adult GU malignancies. Such abnormalities are wide-ranging, affecting the genome at multiple scales, including losses and gains of entire chromosomes or chromosomal arms as well as deletions and amplifications of large and small chromosomal regions. These changes are generically referred to as CNAs. In addition to mutations, structural rearrangements, and epigenetic changes, CNAs are yet another reflection of the underlying genomic instability in cancer cells, resulting in the large number of genetic changes required for malignant transformation. This instability generates a great degree of genetic heterogeneity. For instance, when metaphase chromosomes of tumor cells are examined during karyotypic analysis, a bewildering array of chromosomal aberrations is typically observed, such that no two karyotypes within a given cancer cell population are exactly the same. However, within this seemingly random assortment of alterations, some changes are seen in multiple different cells and multiple tumor samples, providing a strong indication that a gene or genes located in the region undergoing recurrent alteration is involved in the pathogenesis of the disease. Over the past several decades, using ever more sophisticated and higher resolution molecular methods, many such changes have been cataloged and candidate cancer genes have been identified. Two general approaches are used here. In the first, inherited (germline) defects in genes that cause hereditary cancer predisposition syndromes are sought, often by performing genetic linkage analysis in affected and nonaffected family members in an attempt to find genetic loci that track in a mendelian fashion with disease status. Several familial cancer predisposition syndromes are now understood in significant detail, some featuring GU malignancies and others not (Tables 19-1 and 19-2). In the second approach, various techniques are employed to discover disease-associated genes in sporadic cancers that lack a strong familial component (caused by somatic rather than germline genetic alterations). The detection of CNAs in a particular gene (or region containing the gene)

TABLE 19-1 Tumor Syndromes Associated with Genitourinary Malignancies

SYNDROME	TUMOR	CHROMOSOME(S)	GENE(S)	(FUNCTION)
Wilms tumor	Wilms tumor	11p13	<i>WT1</i>	(Transcriptional repressor)
Beckwith-Wiedemann	Wilms tumor	11p15	<i>CDKN1C</i>	(Cell cycle regulator)
von Hippel-Lindau	Clear cell renal carcinoma Pheochromocytoma	3p25	<i>VHL</i>	(Transcriptional elongation and ubiquitination)
Hereditary papillary renal cancer	Papillary renal carcinoma	7q31	<i>MET</i>	(Receptor tyrosine kinase)
Birt-Hogg-Dube	Papillary renal carcinoma Oncocytoma	17p11.2	<i>FLCN</i>	(Unknown function)
MEN type 2	Pheochromocytoma	10q11	<i>RET</i>	(Receptor tyrosine kinase)
Hereditary nonpolyposis colorectal cancer	Upper tract transitional cell carcinoma	2p22, 3p21.3, 2p18, 2q31-q33, 7p22, 14q24.3	<i>MSH2, MLH1, MSH6, PMS1, PMS2, MLH3</i>	(DNA mismatch repair)
Hereditary prostate cancer	Prostate cancer	1q24-25, 1p36, 1q42-43, 8p22-23, 17p11, 20q13, Xq27-28	<i>RNASEL, MSR1, ELAC2</i>	(Endoribonuclease, macrophage specific receptor, cell cycle regulator)

MEN, multiple endocrine neoplasia.

TABLE 19-2 Selected Tumor Syndromes Not Strongly Associated with Genitourinary Malignancies

SYNDROME	PRIMARY TUMOR	CHROMOSOME(S)	GENE(S)	(FUNCTION)
Familial retinoblastoma	Retinoblastoma	13q14	<i>RB</i>	(Transcriptional regulation)
Li-Fraumeni	Sarcoma, breast carcinoma	17p13, 22q12	<i>TP53, hCHK2</i>	(Transcription factor, serine kinase)
Familial adenomatous polyposis	Colorectal carcinoma	5q21	<i>APC</i>	(Regulates β -catenin activity)
Familial breast carcinoma	Breast carcinoma	17q21, 13q12	<i>BRCA1, BRCA2</i>	(DNA double-stranded break repair)
Cowden disease	Breast carcinoma	10q23	<i>PTEN</i>	(Phosphatase; PI3K antagonist)
MEN type 1	Pancreatic islet cell carcinoma	11q13	<i>MEN1</i>	(Transcription factor)

MEN, multiple endocrine neoplasia; PI3K, phosphatidylinositol-3'-kinase.

coupled with mutations in the other allele is persuasive evidence for that gene functioning as a disease-relevant oncogene (with activating mutations) or tumor suppressor gene (featuring inactivating mutations or promoter methylation). In the case of cancer-related genes identified in hereditary predisposition syndromes, one hopes that alterations of genes discovered in familial forms of the disease are also relevant to their more common sporadic counterparts. In many instances, this has been found to be the case; for example, gene abnormalities linked to certain familial forms of kidney cancer are also involved in sporadic forms of the disease. In the following sections, we describe some of the recurrent genetic changes identified in familial and sporadic forms of GU malignancies.

Hereditary Prostate Cancer

Family history is one of the strongest risk factors for prostate cancer (Steinberg et al, 1990), and criteria defining a hereditary form of the disease have been established (Carter et al, 1993). Twin studies have estimated a heritable risk for prostate cancer of approximately 50% (Page et al, 1997; Lichtenstein et al, 2000). Traditional linkage analysis is well suited to identify highly penetrant genetic alterations (Fig. 19-12). The overall low yield and irreproducibility seen in hereditary prostate cancer (HPC) linkage studies has led to the conclusion that rather than being caused by a few high-impact genes, HPC is instead likely to depend on

alterations in many genes, each of which has only a modest effect (Easton et al, 2003; Schaid, 2004).

Initial genome-wide searches in HPC families uncovered evidence for susceptibility loci on chromosomes 1q, 4q, 5p, 7p, 13q, and Xq (Smith et al, 1996). The first strong candidate locus, HPC1, was localized to the region 1q24.25 (Gronberg et al, 1997) and a gene, *RNASEL*, was later identified at this locus (Carpten et al, 2002; Rokman et al, 2002). Although this linkage was replicated in some studies, it was not confirmed in others (Cooney et al, 1997; McIndoe et al, 1997; Eeles et al, 1998; Berghthorsson et al, 2000). Similarly, a failure to confirm linkage consistently has plagued other candidate HPC loci and genes as well, highlighting the difficulty in conducting such studies. Because prostate cancer is a relatively common disease, HPC families are contaminated with sporadic cases ("phenocopies"). It has become apparent that familial prostate cancer may lack the type of high-risk susceptibility genes such as *BRCA1* or *BRCA2* that are clearly linked to hereditary forms of breast and ovarian cancers (Simard et al, 2003). Among other considerations, these facts underline the need for large, well-defined HPC cohorts, making genetic studies difficult to perform. One large HPC cohort of 175 pedigrees identified a region in chromosome 17q21-22 near *BRCA1* with linkage to prostate cancer susceptibility (Lange et al, 2003). This region has subsequently become one of the most intensively investigated regions of the genome for HPC susceptibility. More recently, targeted next-generation sequencing of exons in 202 genes on chromosome 17q21-22 from germline DNA

Figure 19-12. The familial tumor syndrome is passed from generation to generation. Genotyping demonstrates that the polymorphic marker **A** (marked in bold) is passed also from generation to generation in concert with the phenotypic disease. Presumably, a gene responsible for the syndrome is located near marker **A**. Linkage analysis is complicated by incomplete penetrance (not all members of the family with the allele get the disease), phenocopies (family members who have sporadic disease), inability to get DNA from all family members, and the large number of markers being simultaneously analyzed.

of unrelated patients with prostate cancer from families that were selected for linkage to the 17q22-22 region identified a variant in the *HOXB13* gene (*HOXB13* G84E) that significantly increased the risk of HPC (Ewing et al, 2012). The carrier frequency of the G84E allele was found in 0.1% of men without prostate cancer and 1.4% of men with prostate cancer. The frequency of the allele was much higher in men with early-onset, familial prostate cancer (3.1%) compared with men with late-onset, nonfamilial prostate cancer (0.6%) (Ewing et al, 2012). Although the carrier rate of the G84E allele is rare, the strong linkage to prostate cancer risk may warrant genetic testing for the variant, similar to testing that is currently performed for *BRCA1* or *BRCA2* in hereditary breast and ovarian cancers. Other candidate HPC susceptibility genes include *ELAC2* (HPC2), macrophage scavenger receptor-1 (*MSR-1*), and *PODXL* (Tavtigian et al, 2001; Xu et al, 2002a; Nupponen et al, 2004; Casey et al, 2006). It is intriguing that two of the HPC candidates, *RNASEL* and *MSR-1*, are both associated with functions of the immune response because inflammation is currently considered a likely contributor to the pathogenesis of prostate cancer (De Marzo et al, 2007; Sfanos and De Marzo, 2012).

Sporadic Prostate Cancer

In sporadic prostate cancer, initial studies found recurrent changes involving losses of genetic material at 6q, 7q, 8p, 10q, 13q, 16q, 17p, 17q, and 18q; however, in most cases, the precise genes involved have yet to be identified (Karan et al, 2003). Changes in chromosome 8, typically loss of the p arm and gain of the q arm, or portions of these arms, are the most frequently observed genetic alterations. At least two to three separate regions are deleted on 8p, implying the existence of multiple tumor suppressor genes. The region 8p22 is commonly deleted, with frequencies of 32% to 65% reported in primary tumors and 65% to 100% in metastases. *MSR-1* lies in this region, and sequence variants in *MSR-1* have been found to be associated with increased disease risk; however, mutations in *MSR-1* have not been reported in sporadic prostate cancers (Xu et al, 2002a; Nupponen et al, 2004; Wiklund et al, 2009). Another promising candidate tumor suppressor gene on 8p is the prostate-restricted homeobox gene *NKX3.1* at 8p21 (He et al, 1997). Mice engineered with a loss of a single allele of *NKX3.1* develop prostate hyperplasia and PIN, an example of haploinsufficiency, wherein a phenotypic effect is observed secondary

to the loss of a single allele (Bhatia-Gaur et al, 1999; Abdulkadir et al, 2002).

The most common chromosomal abnormality found in advanced prostate cancer (e.g., hormone-refractory lymph node metastases) is 8q gain, often involving the entire chromosomal arm leading to isochromosome 8q formation, and it is correlated with disease progression and resistance to hormone deprivation or blockade (Alers et al, 2000; Isaacs, 2002; van Dekken et al, 2003). The proto-oncogene *MYC* at 8q24 is a likely candidate gene on 8q, but the observed gains are large, and more work is required to assess this possibility properly. Elevated expression of another gene in this region, *EIF3S3*, has been documented in cancer compared with benign prostatic hyperplasia (Savinainen et al, 2004). Mouse models lend support for a linkage to *MYC*; transgenic mice with forced prostate-specific expression of human *MYC* develop PIN and invasive adenocarcinomas (Ellwood-Yen et al, 2003). Amplification at the *MYC* locus has been reported in some human prostate cancers and is associated with a poor prognosis (Jenkins et al, 1997; Sato et al, 1999).

Chromosome 7 abnormalities are also frequently observed in prostate cancer. Aneusomy of the entire chromosome (trisomy 7) has been reported in both PIN and cancer and has been associated with advanced stage and a poor prognosis (Arps et al, 1993; Macoska et al, 1993; Alcaraz et al, 1994; Zitzelsberger et al, 1994; Qian et al, 1995). Apart from whole chromosome gains, losses involving 7q31.1 have been documented, suggesting a tumor suppressor resides here (Zenklusen et al, 1994; Takahashi et al, 1995). A potential candidate tumor suppressor gene in this region is caveolin (*CAV1*), whose expression is reportedly decreased in cancer (Bender et al, 2000; Wiechen et al, 2001). However, positive IHC staining for caveolin has been associated with poor prognosis, and its role in prostate cancer remains unclear (Yang et al, 1999; Tahir et al, 2001). Another attractive candidate gene in this region is *EZH2*, which codes for a histone methyltransferase involved in gene silencing. In microarray analyses, *EZH2* has been found to be overexpressed in prostate cancer metastases, and its expression in primary tumors is associated with disease (PSA) recurrence (Varambally et al, 2002; Rhodes et al, 2003; Lapointe et al, 2004).

Chromosome 10 also undergoes alteration in prostate cancer, with deletions observed at 10p11.2 and 10q23-q24 (Ittmann, 1996; Trybus et al, 1996). The tumor suppressor gene *PTEN*, a phosphatidylinositol-3' (PI3) kinase antagonist, maps to this

second region and has been linked to human prostate cancer in many studies (Li et al, 1997a; Ayala et al, 2004). *PTEN* undergoes homozygous (both copies) deletion, LOH, and promoter hypermethylation and is mutated in prostate cancer. Overall, *PTEN* is more frequently altered in advanced disease (reported rates of 60% to 100%) compared with primary tumors (Cairns et al, 1997; Pesche et al, 1998; Whang et al, 1998; Han et al, 2009; Sarker et al, 2009). The frequency of *PTEN* LOH greatly exceeds *PTEN* mutation, and it is suggested that another gene or genes may be targeted for deletion in this region of chromosome 10. One possibility is the *MXI1* gene, whose protein product binds to and antagonizes *MYC*. In mice, *PTEN* deficiency exhibits synergy when combined with other mouse models of prostate cancer (Di Cristofano et al, 2001; Kim et al, 2002; Chen et al, 2006; Carver et al, 2009; King et al, 2009).

LOH on 13q has been reported in greater than 50% of prostate cases examined. Three separate regions of loss have been identified, containing the potential cancer genes *BRCA2*, *RB1*, *EDNRB*, and *KLF5* (Cooney et al, 1996b; Hyytinen et al, 1999; Chen et al, 2003). High rates of *RB1* loss (up to 80%) have been reported in advanced cancers (Cher et al, 1996); however, the *RB1* mutation rate is relatively low, and *RB1* expression is not well correlated with the gene dosage or disease status (Bookstein et al, 1990; Kubota et al, 1995; Ittmann and Wiczorek, 1996; Kibel and Isaacs, 2000). However, Theodorescu and associates (1997) reported that low *RB1* protein expression was correlated with decreased disease-specific survival in univariate and multivariate analysis.

Losses on 16q have been observed with reported frequencies ranging from 30% to 56% of prostate cancer cases, being more commonly seen in advanced cancer and associated with a poor prognosis (Carter et al, 1990; Bergerheim et al, 1991; Suzuki et al, 1996; Elo et al, 1997; Li et al, 1999). A common region of loss at 16q22-q24 contains two likely candidate genes, the *CDH1* gene at 16q22.1 that codes for the calcium-dependent cell-cell adhesion protein E-cadherin (Morton et al, 1993; Umbas et al, 1994; Murant et al, 2000; Rubin et al, 2001), and the *ATBF1* gene at 16q22, coding for an AT-sequence binding transcription factor (Sun et al, 2005). Loss of *CDH1* has been associated with metastatic prostate cancer; however, IHC staining studies have produced mixed results, and reports of mutation or LOH of E-cadherin are lacking; *CDH1* may not be the primary target of the 16q deletion. The *ATBF1* gene has been reported to be mutated in 40% of prostate cancers (Sun et al, 2005).

Reports of LOH on 6q range from 30% to 50%, with a minimal region of loss at 6q14-q22. No strong candidate gene has been identified in this region (Cooney et al, 1996a; Hyytinen et al, 2002).

Allelic losses of a region on 17p that includes the *TP53* gene have been documented but are infrequent in primary prostate cancer compared with more advanced disease (Brooks et al, 1996). This matches findings of mutational analyses in which *TP53* mutations are rarely found in primary tumors but are reported in 40% of advanced disease (Visakorpi et al, 1992; Bookstein et al, 1993; Navone et al, 1993). A recurrent region of loss on 17q is located near the *BRCA1* gene at 17q21; however, the identified common area of loss does not include this critical tumor suppressor gene (Brothman et al, 1995; Williams et al, 1996).

Deletions on 18q are mainly observed in advanced prostate cancer. A common region of deletion encompasses the known cancer-related genes *DCC*, *SMAD2*, and *SMAD4* (Ueda et al, 1997; Yin et al, 2001).

Loss of the cell cycle regulatory gene *CDKN2A* on 9p21, which encodes the CDKI p16, has been reported in 20% of prostate cancers and at twice this frequency in advanced disease (Cairns et al, 1995; Jarrard et al, 1997). As discussed previously, this locus also contains the p14 and p15 genes, making it difficult to pinpoint the exact target or targets of genetic loss in this region. Reduced expression and LOH of another CDKI gene, *CDKN1B* on 12p13.1-p12, which encodes the p27 protein, are also found in prostate cancer and are associated with more advanced disease (Guo et al, 1997; Kibel et al, 1998; Yang et al, 1998).

One additional locus that has particular relevance for prostate cancer is the androgen receptor (*AR*) gene located on Xq12. The region Xq11-q13 containing *AR* is amplified in 30% of cases of advanced disease failing hormonal ablation therapy, in stark contrast to untreated (hormonally naive) cases that do not show *AR* amplification (Visakorpi et al, 1995a; Chen et al, 2004; Linja and Visakorpi, 2004; Mellado et al, 2009). *AR* mutations, which often act to broaden the receptor's ligand specificity or otherwise provide a gain of function, occur in both advanced and lower stage cancer, although they are rarely found in cases untreated by androgen deprivation therapy (Newmark et al, 1992; Taplin et al, 1995; Tilley et al, 1996; Culig et al, 2001; Hara et al, 2003; Gottlieb et al, 2004). Even in the absence of gene amplification, *AR* protein levels have been seen to be elevated in prostate cancer (Latil et al, 2001; Linja et al, 2001), further emphasizing the importance of *AR* hyperactivation in this disease. In addition to mutation, alternatively spliced versions of the *AR* gene lacking the androgen ligand-binding domain have been identified in prostate cancer cells (Dehm et al, 2008; Guo et al, 2009b; Hu et al, 2009). Such *AR* splice variants are active in the absence of bound ligand and may contribute to the emergence of prostate cancer refractory to androgen ablative therapies.

Subsequent studies using the comparative genomic hybridization (CGH) technique, in which competitive reactions between differentially labeled tumor-derived versus normal-derived genomic DNA highlight regions lost or gained in the tumor sample, have largely confirmed as well as extended the genomic alterations previously uncovered using LOH analysis. These CGH studies indicate that the number of different alterations is increased in advanced disease and that losses are more frequent than gains in early stages of the disease, with gains and genetic amplifications more commonly seen in advanced hormone-refractory disease (Visakorpi et al, 1995b; Cher et al, 1996; Nupponen and Visakorpi, 2000). Sun and coworkers (2007) reviewed all published prostate cancer CGH studies and found that, overall, 13 regions were found to be altered in at least 10% of prostate cancer cases, with 8 regions showing deletion and 5 regions showing copy number gain. An additional six regions (three with gains, three with losses) were found to be altered in greater than 10% of advanced cancers. In agreement with earlier studies, 8p was the most frequent region of genomic loss (with a peak at 8p21.3), being observed in one third of all cases and one half of cases of advanced disease. Likewise, 8q was gained most often (bimodal peaks at 8q22.2 and 8q24.13), being observed in one quarter of all cases and one half of cases of advanced disease (Sun et al, 2007). The other regions commonly lost, in decreasing order of frequency, included 13q21.q31, 6q14.1-q21, 16q13-q24.3, and 18q12.1-q23; regions exhibiting gain included 7q11.21-q32.3, Xq11.1-q23, 17q24.1-q25.3, and 3q26.23-q33. Also in keeping with the general observation that more aggressive and advanced cancers typically harbor more genetic abnormalities than their lower grade and lower stage counterparts, advanced prostate cancers displayed twofold to threefold more CNAs.

The application of modern high-resolution methods for assessing CNA, such as representational oligonucleotide microarray analysis and single nucleotide polymorphism (SNP) mapping arrays, will vastly improve our ability to detect CNA, particularly smaller alterations below the resolution limit of CGH, as well as aid in the identification of the resident oncogenes and tumor suppressor genes (Lucito et al, 2003; Sebat et al, 2004; Slater et al, 2005; Zhao et al, 2005; Liu et al, 2006).

High-density SNP microarrays have been used in genome-wide association studies (GWAS), high-resolution association studies between common DNA sequence variants (SNPs) and prostate cancer risk. In contrast to the more traditional linkage analyses of the past, the new platform is amenable to very large cohorts and is better able to detect genetic variations with small to moderate effects on disease risk (Risch and Merikangas, 1996; Jorgenson and Witte, 2007; Manolio, 2010). To date, several GWAS have been published on prostate cancer, resulting in the identification of more than 70 germline variants (SNPs) that are associated

with the risk of developing prostate cancer (Amundadottir et al, 2006; Duggan et al, 2007; Gudmundsson et al, 2007; Haiman et al, 2007; Witte, 2007; Eeles et al, 2008; Gudmundsson et al, 2008; Thomas et al, 2008; Breyer et al, 2009; Eeles et al, 2009; Yeager et al, 2009; Nakagawa et al, 2012; Eeles et al, 2013). With larger meta-analyses being conducted worldwide, the number of prostate cancer SNPs is expected to increase to greater than 100 in the near future (Nakagawa, 2013). Most of the SNPs are not located in or even near genes previously shown to be involved in prostate cancer pathogenesis. Three independent loci were identified on 8q24, all contained within a 1-Mb DNA segment; however, no genes have been identified yet to account for these risk alleles (Cheng et al, 2008). A systematic review of replication studies in prostate cancer susceptibility loci identified from GWAS found that the 8q24 region continues to be the most implicated in prostate cancer risk and among different racial cohorts (Ishak and Giri, 2011). Although the *MYC* gene is in this vicinity, it is still 200 kb away from the nearest SNP, and its relevance, if any, remains uncertain. In contrast to the loci identified in earlier linkage studies in HPC families, the risk alleles identified in these GWAS have been independently confirmed. As predicted, the risk attributable to each locus is small to modest; however, because of the large cohorts studied, each association is highly statistically significant, and each has been shown to confer risk independent of the other loci. These risk alleles act in a fairly additive fashion (Kote-Jarai et al, 2008; Sun et al, 2008; Zheng et al, 2008; Witte, 2009). The clinical utility of using SNP “panels” for prostate cancer risk assessment is currently being investigated (Nam et al, 2009; Zheng et al, 2009; Chatterjee et al, 2013). However, although men in the top decile in terms of number of combined risk alleles have a twofold to fourfold increased risk for prostate cancer compared with the bottom decile, the numbers of men harboring such large numbers of risk alleles is small, and these SNPs are unlikely to have utility for population screening purposes. An important facet to these studies is that so far most of these prostate cancer risk alleles do not appear to be associated specifically with risk for aggressive disease (Kader et al, 2009; Wiklund et al, 2009). The lack of strong prognostic markers is a key shortcoming in the field that desperately needs to be resolved. Most current GWAS used case-control designs. New case-case studies comparing aggressive versus nonaggressive disease will likely be required to uncover new SNPs informative for disease aggressiveness. It is thought that the recently identified SNPs are more likely related to prostate cancer initiation rather than progression. One such study that compared SNP frequencies among patients with prostate cancer who were defined as having aggressive versus nonaggressive disease identified a region of 17p12 (TT genotype of SNP rs4054823) that was consistently higher among patients with more aggressive disease (Xu et al, 2010). The SNP in 17p12 resides in a region that does not contain any known genes; at the present time, the molecular mechanism by which it is associated with aggressive disease remains unknown. **Another approach that has had some early success in other cancers is to use gene expression array data to develop “gene signatures” able to predict aggressive behavior** (Cheville et al, 2008; Mucci et al, 2008; Setlur et al, 2008).

More recent rapid advances in next-generation sequencing technologies, allowing for whole genome sequencing and whole exome sequencing of multiple tumor samples at a time, have enabled comprehensive analyses of the complete landscape of genomic alterations (e.g., SNPs, CNAs, chromosomal rearrangements) present in human prostate cancer. One such study that conducted massively parallel sequencing of tumor and matched genomic DNA from seven patients with Gleason grade 7 or higher tumors identified a median of 3866 putative somatic base mutations (range 3192 to 5865) covering approximately 80% of the genome per tumor with a 10-fold higher mutation rate in CpG dinucleotides than in all other genomic positions (Berger et al, 2011). Of the somatic mutations identified, a median of 20 mutations per tumor that cause a change in amino acid sequence were found to occur within protein-coding genes. Specific genes found to be mutated in multiple tumors included the scaffold protein *SPTA1*; a modulator of

the transcriptional regulator DAXX called *SPOP*; chromatin modifiers *CHD1*, *CHD5*, and *HDAC9*; and members of the heat shock protein (HSP1) stress response complex *HSPA2*, *HSPA5*, and *HSP90AB1*. In addition to somatic mutations, a median of 90 chromosomal rearrangements were identified per tumor genome (range 43 to 213), all of which produced balanced translocations without genomic loss and with the generation of “chimeric” chromosomes. Additional genes found to be specifically targeted by mutation or rearrangements were the tumor suppressor *PTEN* and the *PTEN*-interacting protein *MAGI2*. In a separate study of whole exome sequencing of 112 prostate tumor and normal pairs, mutations in *SPOP* were again detected, and this was found to be the most frequently mutated gene (Barbieri et al, 2012). Barbieri and colleagues found that *SPOP* mutations occurred in the tumors that lacked ETS family gene rearrangements, possibly defining a new molecular subtype of prostate cancer. Additional recurrent mutations were identified in the forkhead transcription factor gene *FOXA1* and *MED12*, a protein involved in transcription initiation. As exome sequencing becomes increasingly more routine, attention has turned to the possibility of performing rapid high-throughput sequencing of patient samples that can inform therapeutic decisions on men with a new diagnosis of advanced prostate cancer (Roychowdhury et al, 2011).

In addition to novel gene fusions that have been identified via RNA-seq analyses, numerous novel noncoding RNA (ncRNA) species have been identified in prostate cancer samples. Much of the focus of ncRNA species in prostate cancer to date has been on microRNA (miRNA) species, which are small (approximately 22 nucleotides) molecules that function in gene silencing and may be linked to prostate cancer aggressiveness, may promote the development of castration resistance, or may serve as markers of prostate cancer stem cells (Bolton et al, 2014). Multiple novel long noncoding RNA (lncRNA) transcripts that may play a functional role in prostate carcinogenesis have also been discovered; lncRNAs are distinguished from small ncRNA species (e.g., miRNAs, small interfering RNAs, and small nucleolar RNAs) in that they are typically greater than 200 nucleotides in length. Although they do not encode for functional peptides, lncRNAs play a role in gene regulation and other cellular processes (Ulitsky and Bartel, 2013). One of the most clinically advanced biomarkers of prostate cancer, *PCA3* (also known as *DD3*), happens to be an lncRNA (Bussemakers et al, 1999). RNA-seq performed on a cohort of 102 prostate tissues and cell lines identified 106 unannotated intergenic RNAs that were differentially expressed between prostate cancer and benign prostate samples (Prensner et al, 2011). One of the top upregulated transcripts, an lncRNA called *PCAT-1*, was markedly upregulated in metastases and was found to act as a target of the Polycomb Repressive Complex 2 (PRC2). *PCAT-1* is located on chromosome 8q24—discussed previously in regard to susceptibility loci in prostate cancer—and is approximately 725 kb upstream of the *c-MYC* oncogene. Another lncRNA identified in this study, *SCHLAP1*, was found in a follow-up study to antagonize chromatin remodeling complex activity and serve as a prognostic indicator of poor prostate cancer outcome (Prensner et al, 2013).

Renal Cancer

RCCs include a spectrum of subtypes and can be subdivided into at least five different categories: clear cell RCC (ccRCC), which account for most adult cases (70% to 80%); papillary RCC, which accounts for most of the remaining adult cases (10% to 20%); chromophobe RCC; collecting duct RCC; and the MiTF/TFE family translocation carcinomas described earlier. In addition, there are more than four inherited forms of RCC. **The genes discovered to have germline mutations that cause these familial forms of the disease have been found to play important roles in sporadic RCC as well** (Coleman, 2008).

Patients with von Hippel-Lindau disease are predisposed to numerous tumor types, notably ccRCC (Coleman, 2008). The finding of consistent losses of 3p in this disease led to the identification of the *VHL* gene located at 3p25-p26; germline mutation of

this gene causes VHL disease (Zbar et al, 1987; Tory et al, 1989; Latif et al, 1993; Stolle et al, 1998). When the *VHL* gene was identified, its status was assessed in sporadic (nonfamilial) RCC, where it was found to be mutated in more than half of sporadic ccRCC cases (Gnarra et al, 1994; Shuin et al, 1994). To date, more than 300 different *VHL* mutations have been cataloged, and ccRCC cases not harboring *VHL* mutations often undergo LOH (deletion) or silencing of the gene by promoter hypermethylation. Altogether, most ccRCCs have compromised *VHL*. The *VHL* protein normally functions as part of a multiprotein complex with elonginB, elonginC, Cul-2 (cullin-2), and Rbx1 (ring box-1), which exhibits E3 ubiquitin ligase activity and targets subunits of the hypoxia-inducible factor-1 (HIF-1) transcription factor for ubiquitination and subsequent proteosomal destruction (Kibel et al, 1995; Iliopoulos et al, 1996; Pause et al, 1997; Kamura et al, 1999; Kaelin, 2002). HIF-1 functions as a master regulator of the cellular response to low oxygen levels. Under normal conditions, specific proline amino acid residues in the two HIF-1 subunits, HIF-1 alpha and HIF-1 beta, are hydroxylated by the oxygen-dependent proline hydroxylase enzymes *EGLN1-3*. This oxygen-dependent modification signals ubiquitination of HIF-1, and HIF-1 is rapidly turned over (Maxwell et al, 1999; Bruick and McKnight, 2001; Ivan et al, 2001; Jaakkola et al, 2001). Under conditions of oxygen deprivation (hypoxia), the prolyl hydroxylases fail to act, and HIF-1 is spared and accumulates, allowing its translocation to the nucleus where it activates numerous target genes, including the glucose transporter *GLUT-1*, the proangiogenic growth factors *PDGF* and *VEGF*, the chemokine *CXCL-1* and its receptor *CXCL4*, transforming growth factor- α , and the hepatocyte growth factor receptor *MET* (Wykoff et al, 2001; Igarashi et al, 2002; Hu et al, 2003; Staller et al, 2003; Linehan et al, 2007). That the HIF-1 pathway is activated in ccRCC is supported by the highly vascular nature of these tumors and the fact that expression of HIF-1 target genes is found to be elevated. In ccRCC, the loss of *VHL* function leads to a state of “pseudohypoxia,” in which the cells respond as if they are being starved for oxygen.

Several of the genes activated by HIF-1 have been singled out for therapeutic targeting, and positive results in clinical trials have led to U.S. Food and Drug Administration (FDA) approval of some of these agents (Linehan, 2002; Hansel and Rini, 2008). For example, the monoclonal anti-vascular endothelial growth factor (VEGF) antibody bevacizumab and the small molecule kinase inhibitors sunitinib and sorafenib, which inhibit both VEGF and platelet-derived growth factor, all have shown improvements in progression-free survival in clinical trials for metastatic RCC, leading in the latter two cases to FDA approval (Hansel and Rini, 2008).

The *VHL*/sporadic ccRCC example epitomizes the potential for translational application of cancer molecular genetics. Work began with studies on a familial cancer, which were translated to the sporadic form of the disease, culminating in the rational design of therapeutic agents against revealed molecular targets, having a positive impact in the clinic.

A second familial form of RCC is hereditary papillary renal carcinoma, the cause of which has been pinpointed to activation of the proto-oncogene tyrosine kinase *c-Met*, which is the cell surface receptor for hepatocyte growth factor (Jeffers et al, 1997). *MET* is located at 7q31-q34, which is notable because most sporadic papillary RCC cases show trisomy of chromosome 7 (Kovacs, 1993). In addition, activating mutations, typically affecting the tyrosine kinase domain and leading to a constitutively active receptor, have been found in sporadic cases (Schmidt et al, 1997).

A third type of hereditary RCC predisposition is Birt-Hogg-Dube (BHD) syndrome. Individuals with BHD syndrome most commonly develop chromophobe RCC, but other forms such as ccRCC, papillary RCC, and benign oncocytomas are also observed (Pavlovich et al, 2002, 2005). The *BHD* gene underlying the disease is located at 17p11.12 and codes for the protein folliculin (Schmidt et al, 2001). A spectrum of disruptive mutations and gene deletions supports a tumor suppressor gene function for folliculin (Khoo et al, 2002; Nickerson et al, 2002; Schmidt et al, 2005; Vocke et al, 2005). The precise function of this protein has not been elucidated,

although evidence indicates it affects both the ERK and Akt/mTOR signaling pathways (Baba et al, 2008).

A fourth, rare familial RCC subtype is hereditary leiomyomatosis renal cell carcinoma (HLRCC), featuring an aggressive form of papillary RCC (Kiuru and Launonen, 2004; Merino et al, 2007; Sudarshan et al, 2007). The cause of HLRCC has been traced to the Fumarate Hydratase gene at 1q42.3-q43, whose protein product acts to convert fumarate to malate in the Krebs cycle. The HIF-1 pathway is again implicated in RCC tumorigenesis because the resulting accumulation of fumarate acts as a competitive inhibitor of the prolyl hydroxylases *EGLN1-3*, preventing modification of HIF-1 subunits, prolonging their half-lives and leading to a pseudohypoxic state, as was the case for mutated *VHL*. In support of this pathogenetic scheme, increased expression of VEGF and a high microvessel density have been found in HLRCC tumors (Isaacs et al, 2005; Pollard et al, 2005).

In 2011, a germline missense substitution was discovered in microphthalmia-associated transcription factor (*MITE*, another member of the MiTF family discussed earlier in regard to MiTF/TFE family translocation carcinomas) that conferred a greater than five-fold increase in risk of developing RCC, melanoma, or both types of cancer (Bertolotto et al, 2011). The germline substitution in codon 318 (E318K) was found to impair SUMOylation of MITE, leading to transcriptional activation of genes that function in the hypoxia pathway (*HIF1A*, *CCR7*, *HMOX1*), the importance of which in RCC has already been discussed.

Bladder Cancer

Although first-degree relatives of patients with bladder cancer are at increased risk of developing the disease, high-risk families are very rare and lack clear mendelian inheritance patterns, precluding classic linkage analysis. Bladder cancer is not considered a familial disease. Instead, it has been proposed that many susceptibility genes likely exist with small to moderate effects on disease risk (Aben et al, 2006; Kiemeny, 2008). More recent attention has turned to the use of GWAS, which are better suited to the discovery of low-penetrance susceptibility loci. The first such studies have been published, and reported susceptibility loci include 8q24.21, near the *MYC* proto-oncogene; 3q28, associated with the *TP53* relative *TP63*; and 5p15.33, which is near the *HTERT* gene coding for the cancer-associated telomere maintenance enzyme telomerase (Kiemeny et al, 2008, 2009; Rafnar et al, 2009; Wang et al, 2009a). Gain of 5p15.33 had previously been identified as being associated with bladder cancer progression (Yamamoto et al, 2007), and reduced or absent *TP63* expression has been associated with disease progression and poor prognosis (Urist et al, 2002; Koga et al, 2003). An additional GWAS reported by Wu and coworkers (2009b) found a missense variant in the prostate stem cell antigen (*PSCA*) gene to be associated with bladder cancer risk in whites and was subsequently shown in a GWAS by Wang and associates (2010) to be associated with bladder cancer risk in a Chinese population. The rs2294008 variant of *PSCA* has also been shown to be significantly associated with gastric cancer in both Japan and China (Sakamoto et al, 2008; Matsuo et al, 2009; Wu et al, 2009a). This mutation is predicted to result in truncation of the first nine amino acids of the *PSCA* protein, and earlier studies reported that *PSCA* mRNA and protein levels are increased in bladder cancer compared with normal urothelium, with mRNA expression serving as an independent predictor of recurrence in superficial bladder cancer (Amara et al, 2001; Elsamman et al, 2006; Wang et al, 2010). Recent years have seen an explosion in large-scale GWAS in Europe and the United States that have now accounted for at least 11 extensively replicated urinary bladder cancer susceptibility loci: 1p13.3 (*GSTM1*), 2q37.1 (*UGT1A* cluster), 3q28 (*TP63*), 4p16.3 (*TMEM129* and *TACC3-FGFR3*), 5p15.33 (*HTERT-CLPTM1L*), 8p22 (*NAT2*), 8q24.21 (*MYC*), 8q24.3 (*PSCA*), 18q12.3 (*SLC14A1*), 19q12 (*CCNE1*), and 22q13.1 (*CBX6*, *APOBEC3A*) (García-Closas et al, 2005; Kiemeny et al, 2008; Rafnar et al, 2009; Wu et al, 2009b; Kiemeny et al, 2010; Rothman et al, 2010; García-Closas et al, 2011; Moore et al, 2011; Rafnar et al, 2011; Tang et al, 2012). Additional loci have been reported more

recently on 3q26.2 and 11p15.5 as well as two suggested regions on 20p12.2 and 6q22.3 (Figuerola et al, 2014). Pathway analysis of five GWAS conducted on bladder cancer cases and controls of European background found the genetic variants associated with bladder cancer to belong to three fundamental cellular processes: metabolic detoxification, mitosis, and clathrin-mediated vesicles (Menashe et al, 2012).

Most (75% to 85%) bladder cancer and cancer-associated lesions seen in the clinic are of superficial type (stages pTa, pTis, pT1). Recurrences after therapy are frequent, requiring diligent surveillance by urine cytology and cystoscopy resulting in frequent resections. In addition, the risk of progression is high. Accurate assessment of risk for recurrence and progression to muscle-invasive disease is critical, and current predictive schemes based on histopathologic features are suboptimal. It is hoped that information at the molecular level will help improve current methods of risk stratification.

Much work has been done to identify genetic alterations in bladder cancer. In general, observed changes fall into two groups: changes that are mostly unrelated to clinical subtype (e.g., changes in chromosome 9 and RAS mutations) and changes that are related to specific grades or stages of the disease (e.g., *FGFR3* mutations in superficial pTa disease, *TP53* and *RB1* alterations in muscle-invasive disease) (Knowles, 2008).

Greater than half of urothelial cell carcinomas of all grades show chromosome 9 alterations; these are commonly losses of the entire chromosome or entire chromosomal arms. LOH events of more restricted regions are also seen, leading to the current consensus that there are multiple tumor suppressor genes located on both chromosomal arms (Tsai et al, 1990; Cairns et al, 1993; Linnenbach et al, 1993). In otherwise near-diploid tumors, complete loss of one copy (monosomy 9) is the only karyotypic abnormality seen (Gibas et al, 1984; Fadl-Elmula et al, 2000). The region at 9p21 containing the genes for the CDKI proteins *INK4B* (p15) and *INK4A* (p16), which suppress the *RB1* pathway, as well as harboring the *TP53*-stabilizing gene *p14ARF* is a strong candidate for bladder cancer tumor suppressor gene locus. This region commonly undergoes LOH or homozygous deletion in bladder cancers, including low-grade and low-stage tumors (Devlin et al, 1994; Orlow et al, 1995; Williamson et al, 1995; Berggren et al, 2003), and mutations have been associated with high-grade disease and tumor progression (Orlow et al, 1999).

At least three different regions of loss have been mapped on 9q, and candidate bladder cancer tumor suppressor genes have been proposed including the patched gene, *PTCH*, at 9q22, which shows mutations and LOH in up to 40% of cancers (McGarvey et al, 1998; Aboulkassim et al, 2003); the region termed DBC1 at 9q32-q33, which exhibits deletion and silencing in approximately 50% of cases (Habuchi et al, 1998; Nishiyama et al, 1999); and 9q34, which exhibits LOH and contains the gene *TSC1* (tuberous sclerosis gene 1), a strong candidate bladder tumor suppressor gene owing to the finding of *TSC1* mutations in conjunction with LOH (Hornigold et al, 1999; Adachi et al, 2003; Knowles et al, 2003). The *TSC1* gene encodes the protein hamartin, which is a phosphorylation target of Akt and functions in negative regulation of mechanistic target of rapamycin (mTOR), a downstream target of the PI3 kinase pathway that is also dysregulated in bladder cancer via inactivation of the PI3 kinase antagonist *PTEN* as well as mutational activation of the p110 catalytic subunit of PI3 kinase, *PIK3CA* (Cairns et al, 1998; Aveyard et al, 1999; Wang et al, 2000).

Noninvasive (superficial, pTa) papillary urothelial cell carcinoma represents a major bladder cancer subgroup at diagnosis. Apart from changes involving chromosome 9, these tumors appear relatively stable with respect to chromosomal structural changes, with losses and gains reported for approximately 12 different chromosomal locations, most in 20% or less of cases examined (Koed et al, 2005; Knowles, 2008). More subtle genetic alterations in oncogenes and tumor suppressor genes also occur with varying frequencies. As reviewed by Knowles (2008), activating mutations in the RAS family of proto-oncogenes (H-RAS, K-RAS, and N-RAS) have been reported in 15% of cases; mutations in

PIK3CA have been reported in 16% of cases; and amplification/overexpression of *CCND1* and *HDM2* have been reported in 10% to 20% and approximately 30% of cases, respectively.

In addition to oncogene activation, inactivation of several tumor suppressor genes by either deletion or promoter hypermethylation has been reported in superficial papillary urothelial cell carcinoma. These genes include several genes on chromosome 9 such as *CDKN2A* (p16), affected in 30% to 60% of cases; *PTCH*, the *DBC1* locus; and *TSC1*, each reportedly affected in 60% of cases (Knowles, 2008).

The most frequently altered tumor suppressor gene in superficial stage Ta disease is the fibroblast growth factor receptor 3 (*FGFR3*), with mutation frequencies approaching 90% of cases reported (Cappellen et al, 1999; Billerey et al, 2001; Sibley et al, 2001; Tomlinson et al, 2007). The most common *FGFR3* mutation is a serine-to-cysteine mutation at amino acid 249, which has been shown to cause constitutive ligand-independent receptor activation secondary to induced receptor dimerization via intermolecular Cys-Cys disulfide bonding (Li et al, 2006). The frequency of *FGFR3* mutations is much lower in higher stage, invasive bladder cancers, and mutations are lacking in the superficial Tis stage (CIS) lesions, which have a high propensity for recurrence and progression to invasive disease. In addition, in stage Ta disease, there is a strong inverse correlation between mutation and tumor grade (Billerey et al, 2001). The high preferential prevalence of *FGFR3* mutations in stage Ta disease suggests an association with low-risk bladder cancer (Tomlinson et al, 2007). In this respect, it is noteworthy that *FGFR3* mutations are also associated with benign tumors of the skin (seborrheic keratoses) (Logie et al, 2005; Hafner et al, 2006). In a prospective study, Hernandez and colleagues (2006) concluded that *FGFR3* mutations are associated with a subgroup of tumors having a good prognosis, and Burger and associates (2008) reported *FGFR3* status is useful in risk stratification for patients with high-grade non-muscle-invasive urothelial cell carcinoma. Finally, there are indications that *FGFR3* mutations and RAS family mutations are mutually exclusive (Jebar et al, 2005; Logie et al, 2005; Hafner et al, 2006). These findings may be rationalized by considering that *FGFR3* itself is known to activate the RAS/RAF/MEK/ERK pathway (Choi et al, 2001). Likewise, reports of mutational exclusivity have been made regarding *FGFR3* and *TP53*, which is mutated in only about 5% of stage pTa cases and is associated with higher grade disease (Bakkar et al, 2003; Zieger et al, 2005). In stage pT1 disease, the frequency of *FGFR3* mutations is lower, and *TP53* mutation frequency is higher; in contrast to stage pTa disease, these mutations are not necessarily mutually exclusive (Bakkar et al, 2003; van Rhijn et al, 2004; Tomlinson et al, 2007).

Although the frequency of chromosome 9 alterations and RAS family mutations is comparable across all grades and stages of bladder cancer, muscle-invasive urothelial carcinomas (stage pT2 and higher) exhibit more genetic alterations (both qualitatively and quantitatively) than lower stage disease, in keeping with the general observation that more aggressive cancers tend to exhibit evidence of greater genetic instability than their less aggressive counterparts. Invasive bladder tumors exhibit a wide range of CNAs across virtually every chromosome, although the gene targets of these changes are largely unknown at the present time (Koed et al, 2005). In a similar vein, Blaveri and colleagues (2005) used cluster analysis of array CGH data to separate bladder tumors of differing stages and grades successfully from one another. In addition, a quantitative measure of the fraction of genome altered was shown to be inversely related to patient survival time in cases with muscle-invasive cancer (Blaveri et al, 2005). Ploidy, another reflection of genomic instability, has been found to be associated with progression from noninvasive to invasive bladder cancer (Holmang et al, 2001). Mutational inactivation of *TP53* is seen in greater than 40% of invasive pT2 tumors, in sharp contrast to the low mutational rate seen in pTa disease, where *TP53* mutation is associated with risk for progression (Fujimoto et al, 1992; Spruck et al, 1994; Uchida et al, 1995; George et al, 2007). Likewise, inactivation of *RB1*, either by LOH or through *INK4A* inactivation, is common in invasive bladder cancer but is infrequent in stage pTa tumors (Cairns et al, 1991;

Benedict et al, 1999; Chatterjee et al, 2004; Shariat et al, 2004). Loss of the region of 10q harboring the *PTEN* tumor suppressor gene is also more frequent in muscle-invasive bladder cancer than in lower stage pTa tumors (Cappellen et al, 1997; Kagan et al, 1998; Aveyard et al, 1999).

Genetic Alterations in Precursor Lesions to Bladder Neoplasia

Urothelial hyperplasias with flat or papillary histomorphology have been proposed to be precursors of low-grade bladder cancers, although this concept is controversial (Chow et al, 2000). In support, Hartmann and associates (1999) reported that, when present, genetic alterations (assayed at 9q21, 9q22, and 17p13) in hyperplasias were also found in superficial papillary tumors from the same patient. Genetic studies on hyperplasias have reported moderate to high frequencies of chromosome 9 alterations, whereas other genetic changes that are associated with aggressive forms of bladder cancer are reportedly infrequent (Chow et al, 2000). Dysplastic urothelial lesions have been found to have frequent changes of chromosome 9 and frequent aneuploidy, and approximately half are *TP53* mutated (Hartmann et al, 2002; Mallofre et al, 2003). The prevalence of changes seen in low-grade intraurothelial neoplasia was lower than that observed in high-grade (CIS) lesions (Hartmann et al, 2002). CIS lesions (pTis) are aggressive, high-grade precursor lesions, exhibiting high rates of recurrence and progression to invasive disease. In contrast to superficial papillary lesions, CIS exhibits frequent (50% to 70%) genetic alterations (LOH) of 4q, 8p, 11p, 13q, and 14q, in addition to several other chromosomal alterations observed at lower but still significant frequencies (Rosin et al, 1995). CIS lesions may be subdivided into primary lesions, which are isolated without associated cancer, and cancer-associated secondary lesions. It has been reported that chromosome 9 changes are infrequent in primary lesions, whereas most secondary lesions exhibit deletions on chromosome 9 (Spruck et al, 1994; Billerey et al, 2001; Hartmann et al, 2002; Hopman et al, 2002).

As expected, given their aggressive nature, *FGFR3* mutation rates are low in CIS, whereas the *TP53* pathway shows frequent alterations. *TP53* mutation occurs in more than half of CIS lesions and is correlated with strong nuclear *TP53* staining by IHC (Hartmann et al, 2002; Hopman et al, 2002). Nuclear *TP53* expression in transitional cell carcinoma has been associated with increased risk of recurrence and death, independent of tumor grade, stage, and lymph node status in patients with transitional cell carcinoma (Lipponen, 1993; Sarkis et al, 1993; Esrig et al, 1994).

Genetic Alterations in Normal and Benign Bladder Urothelium

Given the propensity of bladder cancer to recur, plus the fact that it is often multifocal, it has been proposed that there may be genetic changes in broad areas of the urothelium. Such a hypothesis would be in keeping with the “field cancerization” concept (also known as “field effect”), first put forward by Slaughter and associates in 1953 to help explain the multifocal nature and high local recurrence rates of cancers of the oral cavity as well as the finding of histologically abnormal epithelium in areas adjacent to cancer. These authors proposed that multiple cancer foci arose within a wider field of abnormal epithelium that had been preconditioned by some prior carcinogenic insult, a process they termed *field cancerization*. Genetic changes have been detected in samples of histologically normal-appearing urothelium obtained from surgical samples from patients with cancer. For example, Muto and colleagues (2000) found shared instances of LOH as well as promoter hypermethylation of the *INK4A* gene between normal-appearing areas and tumor areas from the same case. Likewise, Stoehr and coworkers (2005) performed LOH analyses on a large number of cases in which normal-appearing epithelium was isolated by laser capture microdissection. These authors also reported cancer-associated genetic changes in the

normal-appearing urothelium, which in some cases matched the changes found in concurrent cancers in the same case (Stoehr et al, 2005). However, caution is warranted when assessing such results given the possibility of contamination of the normal areas sampled by small multifocal cancer lesions or by pagetoid spread of tumor cells (Junker et al, 2003). A study by Obermann and colleagues (2004) using interphase FISH in tissue sections detected losses involving chromosome 9 in normal-appearing cells, which, from a technical standpoint, should be effective at excluding possible confounding microscopic foci of cancer cells.

Inverted papillomas of the urinary bladder are considered benign entities. In keeping with this benign status, they exhibit infrequent LOH at cancer-associated chromosomal loci as well as infrequent (<10%) mutations of *FGFR3* (Sung et al, 2006; Eiber et al, 2007). In contrast to inverted papillomas, papillary urothelial neoplasia of low malignant potential exhibits high rates (85%) of *FGFR3* mutation (van Rhijn et al, 2002)—a genetic alteration that, as described earlier, is strongly associated with bladder tumors of low stage and low grade. However, a study by Cheng and associates (2004) found frequent LOH at several loci that typically undergo LOH in advanced stages (pT2 or higher).

Molecular Genetics–Based Assays for Bladder Cancer Detection and Surveillance

The large amount of data concerning common genetic alterations in bladder cancer has been exploited to aid in detecting the presence of bladder cancer. One widely used test termed UroVysion (Abbott Molecular/Vysis, Abbott Laboratories, Abbott Park, IL) is a multiplex, multicolor FISH-based assay that features a cocktail of four hybridization probes that assess the status of four chromosomes (Bubendorf et al, 2001; Halling, 2003). Probes specific for the centromeres of chromosomes 3, 7, and 17 provide information on cancer-associated gains of these chromosomes; the fourth probe is specific for 9p21, which harbors the p14 and p16 genes that are often deleted in bladder cancers. This test, approved by the FDA in 2005, is used in conjunction with standard urine cytology in diagnosing suspected cases and monitoring for local recurrence in patients with previous diagnosis and treatment (Halling et al, 2000; Hajdinjak, 2008). In addition, the test may have utility in monitoring response in patients with superficial bladder cancer treated with intravesical bacillus Calmette-Guérin therapy (Kipp et al, 2005) and may be useful in distinguishing inverted papillomas from urothelial carcinoma with inverted growth pattern (Jones et al, 2007).

At the present time, there are six FDA-approved urine-based molecular tests for bladder cancer focused on either genetic or immunochemical targets, and many other potential markers are under development (van Rhijn et al, 2005; Herman et al, 2008; Zwarthoff, 2008; Sullivan et al, 2009). However, although these tests improve on standard urine cytology, they do not supplant it. Finally, Wang and colleagues (2009b) reported the development of a quantitative PCR gene signature for predicting progression in cases of non–muscle-invasive bladder cancer.

Testicular Cancer

TGCTs possess many unique features (Oosterhuis and Looijenga, 2005). These cancers appear to originate from totipotent stem cells, with evidence strongly supporting TGCT initiation in utero, whereby abnormal primordial germ cells (PGCs) or gonocytes are blocked in their differentiation, remaining dormant until puberty. This theory is supported by expression in TGCT of markers closely associated with PGCs, including placental alkaline phosphatase (PLAP), the stem cell factor tyrosine kinase receptor KIT (c-kit), and the transcription factors POU5F1 (Oct3/4) and NANOG that are involved in maintenance of pluripotency or “stemness.” The presumptive common precursors to TGCT are the intratubular germ cell neoplasia unclassified (ITGCNU), which closely resemble PGCs, sharing many of the same markers (PLAP, KIT, POU5F1) (Skakkebaek et al, 1987). ITGCNU, also traditionally referred to as

CIS, although this nomenclature is technically inaccurate, have a very high rate of progression to invasive disease, estimated to be essentially 100% if allowed sufficient time (Linke et al, 2005).

TGCTs are classified into two main categories: seminomas and nonseminomas. A third type, so-called spermatocytic seminomas, are extremely rare and are not discussed here (Ulbricht, 1993). Similar to the TGCT precursor ITGCNU, seminomas closely resemble PGCs/gonocytes, both morphologically and in their expression of molecular markers (positive expression of PLAP, KIT, POU5F1, NANOG, STELLAR, SOX17) (Sperger et al, 2003; de Jong et al, 2008). Nonseminomatous TGCTs resemble embryonic and extraembryonic tissues that have undergone varying extents of differentiation. Nonseminomas include four subtypes. Embryonal carcinomas are similar in many respects to embryonic stem cells, or perhaps primitive ectoderm, and express POU5F1, NANOG, and STELLAR as well as SOX2 (Gopalan et al, 2009a). Extraembryonic differentiation is apparent in yolk sac tumors and choriocarcinomas, whereas somatic tissue differentiation is found in teratomas.

Besides their unique pathogenesis, TGCTs are unique in their responsiveness to treatment modalities that induce DNA damage (e.g., ionizing radiation and cisplatin-based chemotherapy). Most patients are currently curable, including patients with advanced disseminated disease (Einhorn, 2002). This extreme sensitivity to DNA damage is thought to be related to the origins of TGCTs; their normal stem cell counterparts are poised to undergo apoptosis in response to DNA damage, and most TGCTs maintain wild-type *TP53* and apparently intact *DDR* (Kersemakers et al, 2002; Gorgoulis et al, 2005; Bartkova et al, 2007). Responsiveness to therapy in TGCT is inverse to responses seen in most other cancers—that is, sensitivity decreases with increasing differentiation state, such that ITGCNU are eliminated with low-dose radiation, whereas teratomas exhibit resistance to radiation and chemotherapy.

Family history is a strong risk factor for the development of TGCT, stronger than that found in most other cancers (Forman et al, 1992; Westergaard et al, 1996; Czene et al, 2002; Mai et al, 2010). Despite this fact, initial reports of an association between specific losses on Yq and risk were not confirmed later (Krausz and Looijenga, 2008). Genetic polymorphisms in CAG tract length, which codes for polyglutamine repeats in the androgen receptor, were assessed but were not found to be associated with disease risk (Rajpert-De Meyts et al, 2002; Giwercman et al, 2004; Garolla et al, 2005). Linkage analyses and more recent GWAS have not revealed evidence for major TGCT-related genetic loci, implying instead the existence of multiple loci having modest influence (Lutke Holzik et al, 2005; Crockford et al, 2006; Rapley, 2007). However, in two GWAS, Kanetsky and colleagues (2009) and Rapley and associates (2009) reported that common genetic variants at 5q31.3 near sprouty 4 (*SPRY4*, an inhibitor of the mitogen-activated protein kinase signaling pathway) and in the *KITLG* gene region (c-KIT ligand, also known as stem cell factor or steel factor) on 12q22 are significantly associated with TGCT risk, including both seminomas and nonseminomas. Rapley and associates (2009) additionally identified a susceptibility locus on chromosome 6 in an intron of *BAK1*, a gene that promotes apoptosis.

Spontaneous (as opposed to inherited) genetic alterations have been cataloged in TGCTs. Apart from aneuploidy, relatively few genetic changes or gene mutations are found in TGCTs, giving an overall picture of a relatively low level of genetic instability, which may be due largely to the aforementioned intact *DDR* and predominantly wild-type *TP53* status in these cancers (Bignell et al, 2006; Greenman et al, 2007). One recurrent, nearly universal genetic alteration in TGCTs (excluding the rare spermatocytic seminomas) is the previously described gain of 12p, which may involve the *KRAS* gene or genes such as *NANOG* and *STELLAR* located in the stem cell cluster region at 12p13.31. Additional evidence for *KRAS* involvement in TGCTs includes reports of activating mutations in 40% of cases as well as increases in expression in concert with increased gene copy number. *BRAF* mutations have also been identified in TGCTs but are seen to be mutually exclusive to K-Ras overexpression (McIntyre et al, 2005b; Sommerer et al, 2005).

Other changes that have been reported in sporadic TGCTs include gains of material on chromosomes 1, 5, 7, and X and losses on chromosome 18 in both ITGCNU and invasive cancer. Also, losses from chromosomes 4 and 13 plus gain of chromosome 2p are more restricted to invasive cancers (Summersgill et al, 2001).

In seminomas, recurrent gains of 4q12, 16p13, and Xq22 plus losses of 3q29, 11q12.1, and 14q13.2 have been reported (Goddard et al, 2007). The *KIT* gene, whose protein product is a receptor tyrosine kinase also known as CD117, is located at 4q12. *KIT* amplifications have been reported in 24% of seminomas, and gene-specific amplifications have been reported in 17%, but these changes were lacking in nonseminomas and ITGCNU (McIntyre et al, 2005a). Also, mutations in c-kit represent the most common somatic mutations found in seminomas (25% of cases) but are rarely found in nonseminomas (Forbes et al, 2006; Coffey et al, 2008). Despite the apparent lack of c-kit gene amplifications in ITGCNU, activating mutations in *KIT* have been reported, and IHC staining is positive for this entity as well as seminomas, although positive staining is not seen in nonseminomas or spermatocytic seminomas (Tian et al, 1999; Przygodzki et al, 2002; Looijenga et al, 2003; Kemmer et al, 2004; Goddard et al, 2007).

Gains of 17q11.2-q21 have been reported in TGCTs, and this region contains the *ERBB2* receptor tyrosine kinase gene as well as the *GRB7* adapter protein gene. *ERBB2* ties into the RAS pathway, whereas *GRB7* binds to and likely regulates KIT, *ERBB2*, and RAS and is reportedly overexpressed in TGCTs and ITGCNU precursor (Kraggerud et al, 2002; Skotheim et al, 2003).

The above-described results create an emerging picture of derangement of growth-stimulatory protein kinase signaling pathways in TGCT, including activations in the RAS and KIT pathways in most seminomas and nonseminomas (Kemmer et al, 2004; Sommerer et al, 2005). In keeping with the fact that both RAS and KIT activate the PI3 kinase/AKT pathway, activated Akt has also been observed (Kemmer et al, 2004). In addition, the PI3 kinase antagonist PTEN is reported to be frequently inactivated by either mutation or deletion in both seminomas and nonseminomas, further suggesting an important role for activated PI3 kinase/AKT pathway in TGCTs (Di Vizio et al, 2005; Teng et al, 1997).

Normal PGCs undergo programmed erasure of DNA CpG methylation marks and a loss of imprinting. IHC studies using an anti-5-methylcytosine antibody to assess global methylation status in situ confirmed and extended prior reports focusing on specific loci. The newer studies found very low to absent 5-methylcytosine in most ITGCNU and seminomas compared with robust detection of 5-methylcytosine in nonseminomas (Peltomaki, 1991; Smiraglia et al, 2002; Zhang et al, 2005; Netto et al, 2008). These results are supportive of a model for TGCT pathogenesis in which ITGCNU is derived from retained abnormal PGCs that have matured to the point of 5-methylcytosine erasure but before the point in normal PGC development where epigenetic marks are reestablished via de novo DNA methylation. Such observed changes in global methylation do not rule out the existence of hypermethylation at specific gene promoters. For instance, epigenetic silencing of specific genes, such as the tumor suppressor *RASSF1A*, has been reported in seminoma (Koul et al, 2002; Honorio et al, 2003).

TELOMERES AND TELOMERASE

As we have seen, cancer cells exhibit marked genetic, morphologic, and behavioral heterogeneity, a reflection of their underlying genetic complexity and instability. In addition, most cancers display a strong positive association with increasing age. As discussed previously, it has been persuasively argued that an increase over the extremely low baseline mutation rate (a mutator phenotype) is needed for accrual of sufficient mutations to bring about malignant transformation (Loeb, 1991).

Cancer genomes exhibit clear evidence of genetic instability; however, defective DNA maintenance and repair genes do not appear to be major contributors to the development of most sporadic cancers. The source of the genetic instability involved in most

KEY POINTS: GENOMIC ALTERATIONS

- Large variations in chromosome numbers and complex structural rearrangements as well as intratumoral variation in these aberrations are hallmarks of most human solid tumors.
- The extent of chromosomal abnormalities typically correlates with disease severity and aggressiveness.
- Recurrent structural rearrangements occur in prostate (*ETS* gene fusions), renal (MiTF/TFE family translocation carcinomas), and testicular cancers (isochromosome 12p).
- CNAs in a particular gene, coupled with changes in the other allele, are evidence for that gene functioning as a disease-relevant oncogene or tumor suppressor gene.
- Genes discovered to have germline mutations that cause familial forms of cancer may also be involved in the sporadic form of the disease (e.g., *VHL* in ccRCC).
- High-density SNP microarrays have been used in GWAS to identify DNA sequence variants associated with cancer risk.

cancers has been unclear; this has been particularly true of chromosomal instability, a nearly ubiquitous feature of carcinomas. Although alterations in chromosome number may arise via defects in centrosomes or the mitotic spindle checkpoint, little information exists regarding the origins of structural chromosomal abnormalities (Pihan et al, 2003; Roh et al, 2003). An attractive candidate for the source of chromosomal instability in cancer is telomere dysfunction. Telomeres may provide a common link between genetic instability, cellular proliferation, and aging (Shay, 1997; DePinho, 2000).

Telomeres and Chromosomal Instability

Telomeres are structures composed of specialized repetitive DNA complexed with telomere-specific binding proteins, located at the ends of every human chromosome where they function to stabilize and protect the ends (Blackburn, 1991). Telomeric DNA is noncoding and consists of tandem repeats of the 6-base pair sequence TTAGGG (Moyzis et al, 1988; Meyne et al, 1989). In normal human cells, telomere lengths typically range from 6 to 12 kb per chromosome. Telomeres that are too short are dysfunctional (“uncapped”), causing chromosomal destabilization (Karseder, 2003; Saldanha et al, 2003).

Telomeres are dynamic and shorten by approximately 100 base pairs each time a cell divides because of inability of DNA polymerases to replicate terminal DNA sequences completely (Harley et al, 1990; Lindsey et al, 1991). Telomere length is inversely correlated with the number of times a cell has divided (Hastie et al, 1990; Levy et al, 1992). Telomere shortening may also occur as a result of unrepaired single-strand breaks caused by oxidative damage to telomeric DNA (Kruk et al, 1995; von Zglinicki et al, 2000). Conversely, telomeres may be elongated through the action of the telomere synthetic enzyme telomerase or, uncommonly, via a telomerase-independent genetic recombination mechanism termed *alternative lengthening of telomeres* (ALT) (Greider and Blackburn, 1985; Reddel et al, 2001; Heaphy et al, 2011).

Chromosomes with short, dysfunctional telomeres are prone to fusion, leading to the formation of dicentric chromosomes that mis-segregate or break in mitosis during anaphase. The newly generated chromosomal breaks are themselves fusogenic, perpetuating a cycle of chromosome fusion and breakage (McClintock, 1941; Lo et al, 2002). In this way, critically short telomeres initiate chromosomal instability (Artandi and DePinho, 2000; Feldser et al, 2003; Vukovic et al, 2007). Numerous studies support the link between telomere dysfunction and chromosomal instability in human cancers. For example, in head and neck tumors, chromosomes bearing severely short telomeres are associated with chromosomal fusions, rearrangements, anaphase bridges, and multipolar mitoses (Gisselsson et al, 2000).

Telomere Shortening Acts as a Tumor Suppressive Mechanism in Normal Cells

Normal cells closely monitor their telomere lengths. Moderate telomere shortening either signals entry into an irreversible cell cycle arrest termed *replicative senescence* or initiates programmed cell death—responses thought to have evolved as tumor suppressive barriers against abnormal clonal expansion and the development of excessive telomere shortening that would accompany further cell division were it to be allowed to continue (Wright and Shay, 2001). **Progressive telomere shortening acts as a “mitotic clock” counting down cell divisions and signaling cell cycle exit when one or more telomeres reach a threshold length** (Harley et al, 1990).

Forced expression of the enzyme telomerase in presenescent cells counteracts telomere shortening, preventing replicative senescence and endowing the cells with unlimited cell division potential or “immortalization” (Bodnar et al, 1998; Vaziri and Benchimol, 1998). In normal somatic human cells, telomerase activity is stringently repressed, and telomere length will decrease in proliferating cells and can be used as a signal to halt further expansion. **Although the precise mechanisms by which short telomeres trigger senescence and apoptosis are still under study, evidence implicates the tumor suppressors TP53 and RB1 as being involved in the response to shortened telomeres** (Vaziri and Benchimol, 1999). Abrogation of this telomere length checkpoint allows continued cell division and, in the absence of telomerase, severe telomere shortening beyond the minimum length required for proper telomere function, causing telomere uncapping and chromosomal destabilization (Counter et al, 1992).

Telomere shortening presents two important barriers to incipient cancer cells. First, moderate shortening instigates the senescence cell cycle exit or apoptosis. Second, extreme telomere shortening causes chromosomal instability that, although it increases the mutation rate, also tends to result in genetic abnormalities lethal to the cell (Fig. 19-13).

Cancers and Premalignant Lesions Possess Abnormally Short Telomeres

Most human cancer tissues and cancer-derived cell lines examined to date have been found to contain abnormally short telomeres (Hastie et al, 1990; Mehle et al, 1996; Takagi et al, 1999; Furugori et al, 2000; Remes et al, 2000). For example, using a Southern blot technique for bulk telomere length assessment in radical prostatectomy specimens, Sommerfeld and colleagues (1996) and Koenen and colleagues (1998) observed substantial telomere shortening in primary prostate cancer tissues compared with matched adjacent normal-appearing and benign proliferative (benign prostatic hyperplasia) areas. Likewise, results from direct telomere length assessment in archival tissue samples using telomere-specific FISH revealed significantly shorter telomeres in prostate cancer cells compared with their normal epithelial cell counterparts within the same tissue samples (Meeker et al, 2002a).

When examined using high-resolution telomere-specific FISH, premalignant lesions, including lesions of bladder and prostate cancer, tend to have abnormally short telomeres (van Heek et al, 2002; Meeker and Argani, 2004; Meeker et al, 2004; Hansel et al, 2006; Kawai et al, 2007). This finding indicates that telomere loss occurs early in the disease process, at the intraepithelial neoplasia stage, strongly implying a causal role for telomere shortening in carcinogenesis through the initiation of chromosomal instability (O’Shaughnessy et al, 2002). In the prostate, the premalignant precursor is high-grade PIN (Bostwick and Cheng, 2012), most of which (93%) is found to harbor abnormally short telomeres by FISH (Meeker et al, 2002b). In this study, telomere shortening in high-grade PIN foci was restricted to the luminal secretory epithelial cells only, whereas the underlying basal epithelial cells and surrounding stromal cells displayed normal telomere lengths. In a separate study, Vukovic and coworkers (2003) reported significant telomere shortening in 63% of high-grade PIN lesions, with a

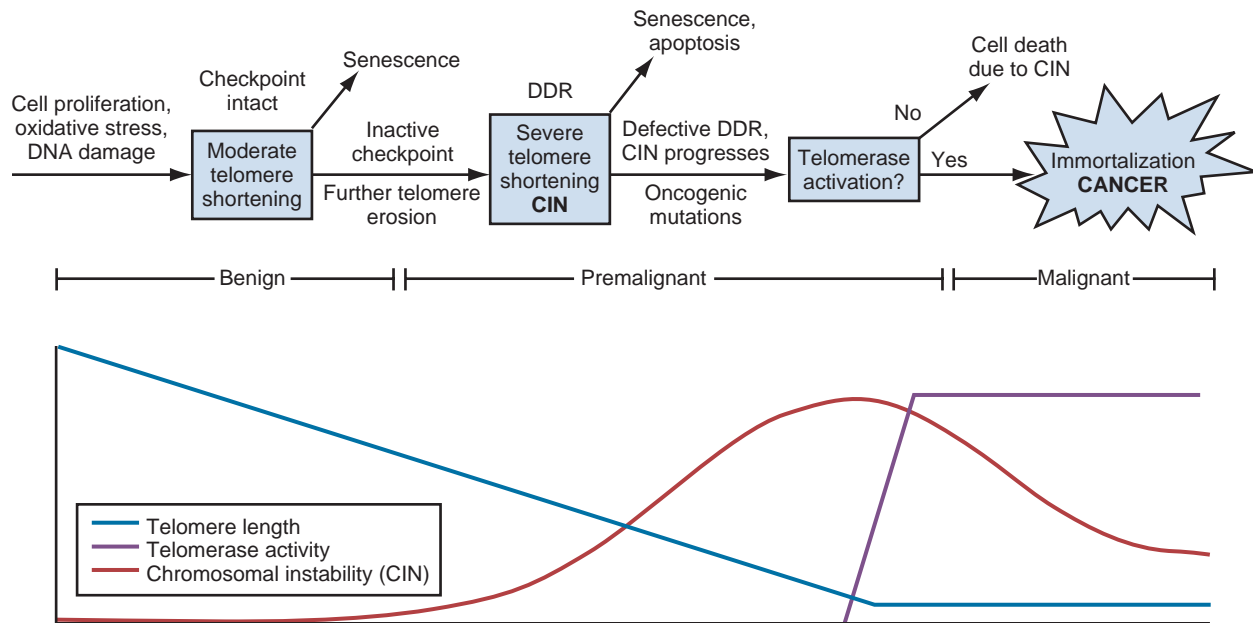

Figure 19-13. Contributions of telomere loss and telomerase activation to oncogenesis. Bypass of the normal telomere length–sensitive cell senescence checkpoint allows severe telomere loss, which initiates chromosomal instability (CIN). Defective DNA damage response (DDR) allows CIN to continue, generating potentially oncogenic mutations but also producing intolerable levels of genomic damage. Transformed cells may proceed through this second barrier by activating telomerase, which stabilizes the telomeres and provides an unlimited proliferative potential (“immortalization”).

higher rate of telomere shortening (80%) reported for foci situated near (within 2 mm) adenocarcinoma within the same tissue sample. Studying a cohort of men with a diagnosis exclusively of high-grade PIN in prostate needle biopsy specimens, Joshua and associates (2007) reported an association between short telomeres in the PIN lesions or surrounding stromal cells and eventual diagnosis of prostate cancer as well as time to diagnosis.

Because most PIN lesions are not thought to progress to invasive cancers, intact telomere-based replicative senescence or apoptosis checkpoints may represent a critical bottleneck restraining the outgrowth of most PIN lesions. Even if incipient cancer cells manage to abrogate these checkpoints, as described subsequently, they would still need to activate telomerase to avoid intolerable levels of genetic instability and provide an immortalized phenotype.

Telomerase Activity Restabilizes Chromosomes and Allows Unlimited Cellular Replication

Although dysfunctional telomeres may help initiate cancer formation, if left unchecked, continued telomere shortening in premalignant lesions and cancers would cause increasing levels of genetic instability ultimately becoming lethal to the tumor. Cancer cells overcome this problem by restabilizing their telomeres, primarily through activation of the enzyme telomerase, a specialized reverse transcriptase that adds back telomere DNA repeats to chromosome ends (Greider and Blackburn, 1987). Telomerase provides at least two critical functions to the tumor cell—quelling chromosomal instability and supplying the capacity for unlimited replication (“immortalization”) (Shay and Wright, 1996; Greider, 1998). Research has revealed that maintenance of telomere length appears to be a necessary step for human cells to become malignant, confirming the long-held belief that cellular immortalization is a key attribute of cancer cells (Hahn et al, 1999; Elenbaas et al, 2001). Although telomerase activity appears to be

the preferred way cancer cells stabilize their telomeres, 10% to 15% of cancer cases in human patients lack detectable telomerase activity. At least a subset of these, particularly certain central nervous system tumors and some cancers of mesenchymal origin, maintain their telomeres via a telomerase-independent genetic recombination pathway known as ALT (Reddel, 2003; Heaphy et al, 2011). With the exceptions of nonseminomatous TGCTs (15%), chromophobe RCC (9%), and small cell carcinoma of the bladder (23%), ALT is rarely if ever observed in common GU malignancies (Heaphy et al, 2011). However, almost all tissue samples assayed for ALT so far have been from primary tumors. Despite a lack of ALT in more than 1000 primary prostate cancers examined, ALT was found in all distant metastases assayed in a single patient with lethal prostate cancer. In this case, detailed genomic analysis indicated that ALT was acquired during the transition from local to disseminated growth, raising the possibility that ALT may play a role in advanced disease (Haffner et al, 2013).

Several studies have reported on telomerase activity in clinical prostate samples with positivity ranging from 47% to 100%, whereas normal and benign prostatic hyperplasia tissues taken from prostates without evidence of cancer are typically negative for telomerase activity (Kim et al, 1994; Sommerfeld et al, 1996; Engelhardt et al, 1997; Kallakury et al, 1997; Lin et al, 1997; Koeneman et al, 1998; Zhang et al, 1998; Wullich et al, 1999; Caldarera et al, 2000; Kamradt et al, 2003). Although two of these studies found a positive correlation between either the presence or the level of telomerase activity and tumor grade, four other studies found no correlation with grade, stage, or preoperative PSA levels. However, the number of cases in many of these studies was small.

Telomerase Activity as a Potential Diagnostic Marker

The high prevalence and relatively strong activity found in prostate cancers compared with normal tissue, plus the very high sensitivity of the standard telomerase activity assay, led to evaluation of the

telomerase activity assay as a potential diagnostic marker for cancer. However, the potential utility of aiding cancer diagnosis appears limited primarily because of problems with both false-negative and false-positive results seen with the technically demanding telomerase activity assay. False-negative results may occur because of inactivation of the labile enzyme during isolation, whereas false-positive results may stem from the presence of inflammatory cells in the sample (Meeker and Coffey, 1997). In addition, other molecular cancer biomarkers often outperform telomerase. For example, the detection of telomerase components by reverse transcriptase PCR in urine provides some improvement in the sensitivity and specificity over urine cytology in bladder cancer detection, particularly in low-grade disease (Eissa et al, 2007). However, a review of the literature on urinary molecular markers for bladder cancer detection concluded that other markers (e.g., microsatellites, FISH, and cytokeratin 20) outperform telomerase (van Rhijn et al, 2005).

Wu and colleagues (2003) found that shorter telomeres in peripheral blood leukocytes (PBLs), as measured with telomere-specific quantitative PCR, were associated with increased risk for many cancers, including bladder and renal cancer. Similar associations between short telomeres and bladder cancer risk were observed when comparing telomere lengths measured in buccal cells and PBLs (Broberg et al, 2005; McGrath et al, 2007). In contrast, no association was observed between PBL telomere length and prostate cancer risk in a study by Mirabello and coworkers (2009). The variations in the PBL telomere lengths measured in these studies are thought to be due to inherited interindividual differences in telomere lengths modified by changes occurring postnatally, perhaps as a result of diet and lifestyle factors.

Potential Prognostic Value of Telomere Length in Prostate Cancer

Telomere shortening has been found to be predictive of poor prognosis in several cancers, including cancers of the lung, endometrium, and breast and neuroblastoma (Smith and Yeh, 1992; Hiyama et al, 1995a; Hiyama et al, 1995b; Griffith et al, 1999; Bisoffi et al, 2006). A potential link between telomere length and prostate cancer prognosis was first reported by Donaldson and associates (1999). In this retrospective case-control study, both biochemical recurrence and overall survival were significantly correlated with tumor telomere content, a surrogate for telomere length. Specifically, all seven patients who underwent prostatectomy whose tumor telomeric DNA contents were less than that of control samples (placental DNA) showed evidence of biochemical recurrence (elevated PSA) within 10 years after surgery (Donaldson et al, 1999). Of the nine patients in this study with short tumor telomeres, seven died within 10 years, in contrast to 100% 10-year survival for patients with normal-to-long tumor telomeres. Additionally, these patients showed no evidence of biochemical recurrence. Potential drawbacks of this study include a small sample size (18 patients; only 7 of 9 men in the short telomere category underwent surgery) and the fact that it was unknown whether the deaths observed were due specifically to prostate cancer. In a more recent retrospective study using 77 prostatectomy samples and a more sensitive chemiluminescent slot blot assay, (Fordyce et al, 2002), it was reported that less-than-normal telomere content in primary prostate cancers was associated with recurrence, independent of patient age, grade (Gleason sum), and regional lymph node status (Fordyce et al, 2005). The magnitude of the relative hazard for disease recurrence associated with low telomere content (relative hazard = 5.02) was on par with that of Gleason grade and nodal status. A positive correlation was found between telomere content of the tumor and telomere content of the surrounding normal-appearing prostate tissue within the same prostatectomy samples. An association was also found between telomere content of these normal-appearing prostate tissues and 72-month recurrence-free survival. The authors postulated that telomere loss in morphologically normal tissue represents areas at heightened risk of experiencing genetic instability; this is reminiscent of the so-called field effect

phenomenon that has long been discussed in the cancer literature (Crissman et al, 1993; Bostwick et al, 1998; Foster et al, 2000; Yu et al, 2004). Fordyce and colleagues (2005) further proposed that cancers arising in such areas may show greater genotypic and phenotypic heterogeneity and be more prone to behave aggressively because of a greater level of chromosomal instability caused by short telomeres. Finally, in a more recent prospective population-based study of prostate cancer using telomere-specific FISH, short telomeres in tumor-associated stroma cells and greater cell-to-cell variability in telomere length among cancer cells were associated with higher risk of death from prostate cancer (Heaphy et al, 2013). These associations were found to be largely independent of other traditional poor prognostic indicators, and the risk associations were essentially additive, such that men with the shortest stromal telomeres and most variable cancer telomeres had a 14-fold increased risk of dying from cancer compared with men with the longest stromal telomeres and the least variable cancer cell telomeres (Heaphy et al, 2013).

Telomerase-Based Opportunities for Therapy

Given that most human tumors rely on telomerase for immortalization and genomic stabilization, this enzyme is an attractive target for anticancer therapy. There are two overall strategic paradigms for therapeutic targeting of telomerase in cancer. The first involves taking advantage of the tumor's dependence on telomerase enzymatic activity for survival. This strategy includes approaches aimed at directly inhibiting telomerase enzymatic activity or blocking its expression. The second approach attempts to exploit the fact that the telomerase gene (*HTERT*) promoter is selectively active in cancer cells, for example, by using the telomerase promoter to drive oncolytic virus or gene therapy vectors to limit their replication or expression to tumor cells or by directing immunotherapy against cells expressing hTERT protein.

Many of these approaches have undergone preclinical testing using prostate cancer cell lines and xenografts, and some are currently in early clinical trials. One point of concern with antitelomerase therapies has to do with the question of selectivity of action against tumor cells over normal telomerase-positive cells, such as the stem cells of the hematopoietic system and cells within tissues with high turnover rates. This question is of particular importance for approaches in which telomerase-positive cells are actively targeted for destruction, including immunotherapy, gene therapy, and oncolytic viral therapies. Work to date describing the treatment of human tumor xenografts in mice in general has not produced major toxicity in normal tissues.

KEY POINTS: TELOMERES AND TELOMERASE

- Telomeres contain stretches of terminal, noncoding, repetitive DNA that cap the ends of each chromosome, stabilizing them.
- Telomere DNA repeats are progressively lost as cells divide and as a result of oxidative DNA damage at the telomeres.
- Normal cells monitor their telomere lengths and permanently exit the cell cycle (cellular senescence) or commit suicide (apoptosis) in tumor suppressive responses to telomere shortening. This telomere length checkpoint involves *TP53* and *RB1*.
- Loss of telomere length checkpoints leads to critical telomere shortening, which initiates chromosomal instability contributing to cancer initiation.
- Most cancers and premalignant lesions have abnormally short telomeres.
- Most cancers express the enzyme telomerase, which restabilizes the telomeres and allows unlimited cell division potential (immortalization), making telomerase an attractive therapeutic target.

APOPTOSIS

Apoptosis, also known as programmed cell death, is a tightly regulated process used by multicellular organisms to eliminate unwanted cells. Apoptosis is used in tissue remodeling during development and in the immune system to eliminate self-reactive T cells (Kerr et al, 1972; Ashkenazi and Dixit, 1998). Apoptosis contrasts sharply with necrosis, a nonprogrammed form of cell death in which cells that are acutely injured (e.g., by physical trauma) swell and burst, abruptly releasing their contents, which act as potent inducers of the inflammatory response. Apoptosis is a more orderly, energy-requiring process in which the contents of the dying cell are degraded and neatly packaged into so-called apoptotic bodies, which are engulfed by neighboring cells or macrophages—a process that does not elicit a strong inflammatory response (Fadok et al, 1992).

Apoptosis and Cancer

In contrast to unicellular organisms, cancer poses a risk to multicellular life forms, and various potentially tumorigenic abnormalities can signal a cell to eliminate itself as a potential threat via apoptosis. For example, if a cell sustains DNA damage (potentially mutagenic) but fails to make repairs, it will be eliminated and replaced from the organism's pool of undamaged cells. Aberrations of apoptosis can be detrimental, and failure of dividing cells to initiate apoptosis contributes to cancer (Ashkenazi and Dixit, 1998).

Abnormalities in the apoptotic machinery have implications for malignancy beyond the ability of an individual cell to respond appropriately to cell physiologic stresses such as DNA damage. First, the apoptosis cascade is critical to the immune system's ability to eliminate cancer cells by inducing them to undergo apoptosis (Nagata, 1997); this has clear implications for both the organism's intrinsic immunosurveillance for malignancy and the tumor's response to extrinsic immunotherapy. Second, because cytotoxic cancer therapies also depend in large part on inducing apoptosis, defects in the apoptosis cascade can profoundly influence tumor responses to chemotherapy and radiotherapy (Walton et al, 1993; Minn et al, 1995; Thornberry and Lazebnik, 1998).

Apoptosis Is an Evolutionarily Conserved Process

Apoptosis is tightly regulated by an evolutionarily conserved system of positive and negative signals, the balance of which determines whether the cell will undergo apoptosis. These signals ultimately converge on an important family of proteases named *caspases* ("cysteine proteases with aspartic acid specificity"), key components of the apoptotic machinery (Thornberry, 1998). Caspases, of which there are at least 13, are broadly categorized as either initiator caspases (e.g., caspase-8, caspase-9, and caspase-10) or executioner caspases (e.g., caspase-3, caspase-6, and caspase-7). Caspases are synthesized as larger, inactive forms called procaspases, which require specific proteolytic cleavage to become active proteases themselves. Often a procaspase is activated by another caspase, setting in motion a sequential, amplifying, proteolytic cascade. Initiator caspases begin the cascade, which ultimately leads to activation of executioner caspases downstream. Once activated, the executioner caspases attack several intracellular protein targets. Executioner caspases cleave antiapoptotic proteins, such as Bcl-2 and Bcl-X_L, which not only destroys their antiapoptotic function but releases pro-apoptotic carboxyl-terminal fragments, further stimulating cell death (Wolf and Green, 1999). Executioner caspases target proteins critical to cell survival. Cleavage of DNA repair and replication proteins, such as DNA-PK ζ and replication factor C, leads to nuclear dysregulation. Nuclear structural proteins, such as lamins NuMa and SAF-A, are fragmented, contributing to dissolution of the nucleus and nuclear condensation, a hallmark of cells undergoing apoptosis. Proteolysis of cytoskeletal proteins such as keratin and actin leads to destruction of the internal structural integrity of the cell. Lastly, cleavage of proteins critical to cell-cell interaction, such as

beta-catenin and focal adhesion kinase, precipitates the specific and irreversible phenotypic changes associated with apoptosis (Orth et al, 1996; Wen et al, 1997; Wolf and Green, 1999). The end result is a stereotypic death in which the cytoplasm shrinks, the cell membrane blebs, and the nuclear chromatin condenses. The entire apoptotic process can be completed in 60 minutes (Thornberry and Lazebnik, 1998).

Additional details of the intrinsic and extrinsic apoptotic pathways can be found on the Expert Consult website.

Role of TP53 in Apoptosis

In addition to the key roles played by TP53 in cell cycle arrest and DNA damage repair, TP53 can also induce apoptosis (May and May, 1999). TP53-induced apoptosis is mediated through the Bcl-2 family, via the intrinsic pathway, and dysregulation of this apoptotic pathway has direct relevance to the etiology of cancer. TP53-induced apoptosis is mediated by transcriptional activation of genes that initiate the apoptotic cascade and inhibition of genes that block the cascade (Miyashita et al, 1994; Miyashita and Reed, 1995; Oda et al, 2000). TP53-induced apoptosis is dependent on the Apaf-1/caspase-9 activation pathway (Soengas et al, 1999). Although the Bcl-2 family member Bax has been implicated as the primary factor responsible for TP53 induction of this cascade (Miyashita and Reed, 1995), Bax is not essential for TP53-dependent apoptosis (Knudson et al, 1995). It is possible that inhibition of Bcl-2 (Miyashita et al, 1994) or upregulation of the pro-apoptotic Bcl-2 family member noxa may still allow cells lacking Bax to undergo TP53-dependent apoptosis (Oda et al, 2000). Considering the role of TP53 in multiple tumor suppressive pathways (DNA damage response, cellular senescence, and apoptosis), it is not surprising that it is so frequently mutated in cancer.

Apoptosis and Genitourinary Malignancies

Because the inability of a tumor cell to undergo apoptosis is a hallmark of malignancy, multiple groups have attempted to characterize the apoptotic response of GU malignancies. Because cells undergoing apoptosis exhibit a stereotypic death, global analysis of apoptosis is possible using assays designed to detect key hallmarks of the apoptotic process, such as the fragmentation of DNA characteristic of the process as well as assays designed to detect abnormalities in specific apoptotic proteins.

Global Defects in Apoptosis

Both high-grade PIN and prostate carcinoma have significantly higher levels of apoptosis than normal prostatic epithelium. The level of apoptotic activity is relatively low compared with other malignancies and is opposed by increased replication. Many prostate cancer cells can be induced to undergo apoptosis in response to androgen withdrawal, which represents a frontline therapy for patients with advanced disease (Kyprianou et al, 1990; Isaacs, 1994; Denmeade and Isaacs, 1996; Tu et al, 1996). However, not all of a patient's cancer cells succumb because recurrences inevitably arise. As the tumor progresses to androgen independence, it is unclear if the androgen-resistant cells have an increased or decreased rate of apoptosis because studies have demonstrated both in hormone-refractory disease (Berges et al, 1995; Koivisto et al, 1997). The conflicting data may reflect both the tumor's dynamics and the effect of therapy. There is a clear survival advantage for the advanced cancer cell that can protect itself from apoptosis. However, a rapidly growing, infiltrative, advanced tumor, which is outgrowing its blood supply and mutating its DNA, may have a high apoptotic rate despite protective mechanisms the tumor's cells have acquired.

Studies of apoptosis in bladder carcinoma have demonstrated an association with aggressive high-grade advanced disease but not with decreased disease-free survival (Lipponen and Aaltomaa, 1994; King et al, 1996). External-beam radiation therapy has been associated with a modest improvement in survival for tumors with high

Intrinsic Apoptotic Pathway

Apoptosis can be initiated via two different routes—the intrinsic and the extrinsic apoptotic pathways (Fig. 19-14). The intrinsic apoptotic pathway monitors conditions within the cell, responding to various forms of stress. Pro-apoptotic signals may arise secondary to unrepaired DNA damage or from a lack of prosurvival signals transduced from cell surface receptors, such as when cell-cell or cell–extracellular matrix contact is disrupted or soluble factors such as hormones or growth factors are withdrawn.

The mitochondrion is a main component of the intrinsic pathway, as is another conserved protein family, the Bcl-2 family. Bcl-2 family members include both pro-apoptotic and antiapoptotic proteins. The pro-apoptotic group consists of at least 12 members, including Bax, Bak, Bok, Bik, Bad, Bid, and Bim. There are at least six antiapoptotic (prosurvival) Bcl-2 family members, including Bcl-2 itself, Bcl-X_L, Bcl-W, and Mcl1 (Adams and Cory, 1998). All members contain one or more Bcl-2 homology domains (BH1 to BH4) that allow members of the family to heterodimerize with each other. Bcl-2 family members regulate each other's function through these BH domains (Chittenden et al, 1995; Cheng et al, 1996). Although each pro-apoptotic Bcl-2 member responds to different stimuli, the principal mechanism by which they induce cell death is by increasing mitochondrial membrane permeability (Kroemer and Reed, 2000). When apoptosis is signaled via the intrinsic pathway, the balance between Bcl-2 family members shifts in favor of pro-apoptotic proteins that increase the permeability of the mitochondrial outer membrane, facilitating the release of cytochrome *c* from the intermembrane space into the cytoplasm (Jurgensmeier et al, 1998; Wolf and Eastman, 1999). Once in the cytoplasm, cytochrome *c* molecules bind to Apaf-1 proteins, forming a complex termed the *apoptosome*. The apoptosome activates caspase-9, one of the initiator caspases, beginning the caspase cascade as described earlier (Li et al, 1997b).

Antiapoptotic Bcl-2 family members block apoptosis by inhibiting the pro-apoptotic family members and, in doing so, decreasing mitochondrial permeability (see Fig. 19-14 on the Expert Consult website) (Li et al, 1997b; Srinivasula et al, 1998).

Bax is the most well studied pro-apoptotic Bcl-2 family member. It is transcriptionally activated by TP53. When activated, Bax dimerizes at the mitochondrial membrane. The dimer forms a channel that facilitates the release of cytochrome *c* from the mitochondria. Bcl-2 is the best studied antiapoptotic Bcl-2 family member. It functions by binding to Bax and, in doing so, blocks Bax-induced mitochondrial permeability (Miyashita et al, 1994; Adams and Cory, 1998).

Other pro-apoptotic family members are activated by various stimuli. Often they function not by inducing mitochondrial permeability directly but by activating or inhibiting other Bcl-2 family members. The first example is Bid. Bid is regulated by initiator caspases. Cytosolic Bid is activated by caspase-8 (see Fig. 19-14); this allows dimerization of Bid with either Bax or Bcl-2. This dimerization activates Bax activity and inhibits Bcl-2. The net result is to tip the balance in favor of apoptosis (Li et al, 1998). Because Bid is activated by caspases, it provides a link between the ligand-induced apoptotic machinery of the extrinsic pathway (described subsequently) and Bcl-2 family members.

An additional level of regulation is provided by IAPs, a family of proteins that act to prevent apoptosis by inhibiting specific caspase proteases, either directly or by inhibiting the conversion from the procaspase to the active form (Deveraux et al, 1998).

Extrinsic Apoptotic Pathway

In addition to the intrinsic pathway, a second pathway termed the *extrinsic pathway* mediates apoptosis after receipt of extracellular signals from cell surface receptors called “death receptors,” such as the tumor necrosis factor receptor TNFR1 and the Fas receptor (Fig. 19-15). These receptors belong to the tumor necrosis factor superfamily and contain a ligand-specific extracellular domain and an intracellular “death domain.” The binding of extracellular signaling molecules to the receptor activates the receptor, which signals through the death domain located on the cytoplasmic portion of the receptor. The death domain allows the receptor to bind to intracellular adapter proteins that also contain a death

Figure 19-14. Cascade of extrinsic and intrinsic mechanisms of apoptosis. The extrinsic system depends on ligand-induced activation of executioner caspases, whereas the intrinsic system depends on the dimerization of BCL2 family members to alter mitochondrial membrane permeability.

Figure 19-15. Example of death receptor-mediated activation of initiator caspases.

domain (e.g., RIP, TRADD, FADD). In addition to their own death domain, the adapter proteins have a death effector domain that allows the adapter protein to bind to the caspase recruitment domain (CARD) of initiator caspases (Ashkenazi and Dixit, 1998). Once bound, the initiator caspases undergo self-cleavage and are then capable of activating effector caspases via the caspase cascade (Li et al, 1998; Muzio, 1998).

The best-characterized death receptor is CD95, or FAS, which appears to play an important role in cancer immunosurveillance (Ashkenazi and Dixit, 1998). The ligand CD95L (also known as FAS ligand) forms a trimer that binds three CD95 receptors (Nagata, 1997). The clustering of CD95 allows the adapter protein FADD to bind to CD95 via their death domains (see Fig. 19-15). Procaspase-8, or FLICE, binds to FADD via the death effector domain. Procaspase-8 oligomerization promotes autoactivation to active caspase-8 (Muzio, 1998). Other initiator procaspases, such as procaspase-10, are activated through similar mechanisms (Vincenz and Dixit, 1997). Negative regulatory molecules, such as FLIP, bind to FADD and in doing so inhibit procaspase-8 binding and apoptosis (Irmeler et al, 1997).

The death receptor pathway does not appear to have a direct role in the etiology of cancer. Patients with hereditary defects in this system and knockout mice both are characterized by T-cell abnormalities and fatal autoimmune syndromes, not hereditary tumor syndromes (Nagata, 1997). However, the identification of ligand-dependent apoptosis receptors may have a profound impact on therapy. Most cancer therapies (i.e., chemotherapy and external-beam radiation therapy) depend on *TP53* to induce apoptosis in the cancer cell. Because *TP53* is mutated in more than half of malignancies (Hollstein et al, 1991), *TP53*-independent pathways for apoptosis are of great clinical interest. Because the ligand-dependent apoptosis described earlier is independent of *p53*, these receptors and ligands are attractive novel treatment targets. Compounds that bind to the receptors are extremely toxic (Nagata, 1997). It is hoped that novel compounds will have improved toxicity profiles.

apoptotic rates. This improved survival may reflect the fact that external-beam radiation therapy requires an intact apoptotic mechanism to be effective (Rodel et al, 2000).

As previously mentioned, most TGCTs maintain intact DDR and wild-type *TP53* and display high cure rates in response to therapies that induce DNA damage (Einhorn, 2002; Kersemaekers et al, 2002; Gorgoulis et al, 2005; Bartkova et al, 2007).

Individual members of the apoptotic machinery have been frequently studied. However, all studies are limited by an inability to assay all elements of the apoptotic machinery simultaneously and to assess globally the ability of the tumor to undergo programmed cell death.

TP53 mutations and abnormalities in expression are among the most frequent in cancer and have been identified in prostate, bladder, and renal cancers (Hollstein et al, 1991; Sidransky et al, 1991; Reiter et al, 1993). Abnormalities in *TP53* cause dysregulation of the cell cycle and DNA repair mechanisms in addition to apoptosis and are covered in more detail in Cell Cycle Deregulation.

Bcl-2 family members have been studied in GU malignancies. Elevated levels of Bcl-2 have been identified in most hormone-refractory prostate tumors, reflecting the tumor's relative resistance to apoptosis in the advanced state (McDonnell et al, 1992; Colombel et al, 1993). Both increased and decreased levels of Bcl-2 have been identified in localized prostate tumors, and a few studies have found a correlation with grade, stage, and progression (Byrne et al, 1997; Lipponen and Vesalainen, 1997; Theodorescu et al, 1997). Other antiapoptotic members of the Bcl-2 gene family, Bcl-X_L and Mcl1, may also be linked to prostate carcinoma (Krajewska et al, 1996). Analysis of bladder carcinoma has demonstrated similar results. Bcl-2 levels are higher in more aggressive bladder carcinoma, but expression of Bcl-2 had no effect on treatment outcome (King et al, 1996; Rodel et al, 2000). As noted earlier, phosphorylation of Bad by Akt can also tilt the scales toward cell survival, especially in concert with elevated levels of Bcl-2. Akt activation is commonly seen in many urologic malignancies and can result from loss of the tumor suppressor *PTEN*; mutation and constitutive activation of PI3 kinase; or activation of tyrosine kinase receptors such as HER2/NEU, EGFR, and insulin-like growth factor receptor.

Other Bcl-2 family members have not been as well studied. Loss of Bax expression is apparently an uncommon mechanism for the development of prostate carcinoma (Krajewska et al, 1996; Johnson and Hamdy, 1998), but it may play a role in progression of localized bladder carcinoma (Ye et al, 1998).

Deficiencies in signal transduction pathways leading to apoptosis play a role in the initiation and progression of malignancy. It is unclear if expression analysis of the apoptotic machinery will provide additional prognostic information than that provided by traditional histochemical analysis. However, it is clear that effective chemotherapy and radiation therapy are largely dependent on apoptosis. In addition, in the future the apoptotic machinery may be manipulated using novel ligands that bind to death receptors and promote *TP53*-independent cancer cell death.

Alternative Regulators of Apoptosis in Genitourinary Malignancies

In addition to the classic regulators of apoptosis, numerous other pathways for cell survival and death have been uncovered that play key roles in urologic cancer. Some of these pathways are being actively explored as targets for cancer therapy. The Vancouver group mapped out a detailed gene profile of prostate tumors treated with neoadjuvant hormonal ablation therapy to identify key regulators of cell death and survival after castration. In addition to Bcl-2, which is upregulated in surviving cancer cells, they also reported on clusterin and Hsp27. Clusterin, or TRPM2 (testosterone repressed prostate message-2), is upregulated both in patient samples after hormone ablation and in the Shionogi and CWR-22 xenograft models of hormone-sensitive tumors. Although its precise

function is unknown, a large body of evidence suggests that clusterin is induced by stress and functions to stabilize the cell during periods of stress (Miyake et al, 2000). In this model, clusterin is believed to act like heat shock proteins, whose role as a protein chaperone is also to stabilize client proteins. Clusterin is activated by HSP1. Functional evidence of the role of clusterin comes from studies in which clusterin is either overexpressed or knocked down using antisense strategies. In the first scenario, clusterin expression promotes hormone-refractory cell growth and prevents androgen withdrawal-induced apoptosis. In the second scenario, treatment of hormone-refractory cells with antisense clusterin promotes apoptosis (July et al, 2002; Miyake et al, 2004; Gleave and Miyake, 2005). This same group of investigators also reported that the heat shock protein HSP27 is frequently overexpressed in hormone-refractory prostate cancers. Similar experiments using overexpression and antisense strategies have suggested that targeting HSP27 may influence the course of hormone-refractory cancers, in particular in combination with cytotoxic chemotherapies (Rocchi et al, 2004).

Another family of cellular signaling molecules that play a role in the regulation of cell survival and apoptosis is the sphingolipids. Sphingolipids are one of three major constituents of the cell membrane, alongside phospholipids and cholesterol. Sphingolipid generation is regulated by a large cast of enzymes, notably the sphingomyelinases, ceramide synthase, and the ceramidases. Ceramide is produced from sphingomyelin by sphingomyelinase and from sphinganine by ceramide synthase. Ceramidases degrade ceramide and lead to formation of sphingosine and sphingosine-1-phosphate. Ceramide is a potent pro-apoptotic molecule that can promote apoptosis through the classic mitochondrial activation of caspases or through a nonclassic caspase-independent form of apoptosis (Kolesnick and Fuks, 2003). Sphingosine-1-phosphate, in contrast, is a powerful antiapoptotic molecule that may modulate the degree of apoptosis similar to a rheostat (Maceyka et al, 2002).

The importance of ceramide to GU tumors is that it appears to be a key modulator of radiation-induced tissue damage and apoptosis. Similar to clusterin and other heat shock proteins, ceramide appears to be a critical mediator of stress response in cells, in this case promoting apoptosis as opposed to cell survival. Studies supporting the role of ceramide in radiation-induced apoptosis are manifold, including studies demonstrating the direct cell death signal induced by exogenous treatment of cells with ceramide, studies of radiation response in mouse knockout models, and studies of radiation response in the presence and absence of inhibitors of sphingolipid metabolism. It is hoped that therapeutics that increase ceramide production and promote apoptosis can be developed. The role of sphingolipid-1-phosphate has also emerged from these studies, and work from several investigators suggests that this molecule is a promising target for cancer therapy (Gulbins and Kolesnick, 2003; Kester and Kolesnick, 2003; Perry and Kolesnick, 2003).

STEM CELLS AND CANCER

Stem cells are found in multicellular organisms and are characterized by the ability of self-renewal through mitotic cell division and differentiation into a diverse range of specialized cell types. Common properties of stem cells include the ability of self-renewal, generation of cellular progeny, localization within specialized niches, and the ability to give rise to all cell types within an organ. For example, human prostate stem cells are believed to be localized within the basal epithelium and give rise to a hierarchy of progenitor cells that may differentiate into secretory or neuroendocrine cells (Burger et al, 2005; Xin et al, 2005).

Studies suggest that neoplastic cells mimic normal tissue development and may arise from and are dependent on a small population of stem cells. The cancer stem cell hypothesis argues that cancers arise from transformation of stem or progenitor cells that are capable of multilineage differentiation. Cancer stem cells may account for only a small percentage of any tumor, but this

KEY POINTS: APOPTOSIS

- Apoptosis is a rapid, orderly programmed form of cell death that is used by multicellular organisms to eliminate unwanted cells.
- Apoptosis is believed to play an important role in tumor suppression because many of the signals that induce apoptosis arise from potentially tumorigenic cell stresses such as DNA damage.
- Cancer is characterized by interruptions in the normal process of apoptosis, resulting in inappropriate cell survival.
- Apoptosis is mediated by a conserved family of proteases known as caspases. Initiator caspases start caspase proteolytic cascades terminating in the activation of executioner caspases that target several cellular proteins.
- Two main apoptotic pathways have been identified. In the intrinsic pathway, Bcl-2 family members modulate the release of cytochrome *c* from the mitochondria, which participates in the activation of initiator caspases. The extrinsic pathway activates caspases in response to signals from extracellular “death receptors.”
- In addition to its functions in cell cycle arrest and DNA repair, *TP53* plays a key role in apoptosis.
- Bcl-2 is a classic inhibitor of the mitochondrial pathway of apoptosis and is overexpressed in some GU malignancies.
- Therapeutic response often depends on the integrity of apoptotic pathways in the cancer cells. Most TGCTs retain intact DDR, wild-type *TP53*, and apoptotic responses, providing high cure rates with DNA-damaging agents.
- Novel agonists and antagonists of apoptosis, such as ceramide and clusterin, may successfully be controlled to combat cancer.

small population of cells is critical for tumor survival. The most readily accepted experimental demonstration of cancer stem cells relies on serial transplantation of tumor cell populations isolated based on one or numerous putative cancer stem cell markers into immune-deficient mice or three-dimensional culture systems and recapitulation of the heterogeneous primary tumor. Using this experimental strategy, initial evidence to support the cancer stem cell hypothesis was discovered in leukemia, breast cancer, and neurologic cancers. For example, a CD44⁺/CD24^{low} population of cells in primary breast tumors was specifically capable of new tumor formation when engrafted into nude mice (Al-Hajj et al, 2003; Dontu et al, 2003). Similar reports in glioblastoma suggest that a CD133⁺ population is the putative stem cell (Singh et al, 2003; Dirks, 2005). One challenge in cancer stem cell research is the lack of any one marker that is exclusively expressed by cancer stem cells. For any given tumor type, typically many different markers can be identified that confer a cancer stem cell phenotype, and absence of the marker does not always imply that a cell is not a cancer stem cell. For example, in glioblastoma, both CD133⁺ and CD133⁻ cell populations have been shown to possess cancer stem cell-like properties (Beier et al, 2007).

A tumor-initiating cell (T-IC) subpopulation has also been identified in human bladder cancer. This group of cells was found to express CD44⁺/CK5⁺/CK20⁻ markers similar to normal bladder basal cells (Chan et al, 2009). The bladder T-IC subpopulation was also capable of forming xenograft tumors in vivo that recapitulated characteristics of the original tumor. CD47 was highly expressed in

this group of cells, and blockade of CD47 resulted in macrophage engulfment of bladder cancer stem cells in vitro. This finding suggests a potential role for therapeutic targeting of CD47 and the T-IC subpopulation in bladder cancer (Chan et al, 2009). To date, numerous other putative cancer stem cell populations have been identified in bladder cancer, including CK17⁺/67LR⁺/CAECAM⁻ cells, embryonic stem cell marker *POU5F1*⁺ cells, and high aldehyde dehydrogenase activity (ALDH^{hi}) cells (van der Horst et al, 2012).

KEY POINTS: STEM CELLS AND CANCER

- Stem cells are defined by their ability to differentiate along multiple lineages and their immortality.
- Cancer is believed to be a stem cell disease in which a small population of cancer stem cells maintains the larger tumor.
- Cancer may ultimately be eradicated by targeting only the cancer stem cell.

The field of urology was the earliest to gain from the advent of transplantation, with the kidney being the first entire organ to be replaced in a human, in 1955 (Guild et al, 1955). In the early 1960s, Murray, who later received the Nobel Prize for his work, performed a nonrelated kidney transplantation from a non-genetically identical patient into another. This transplant, which overcame the immunologic barrier, marked a new era in medical therapy and opened the door for use of transplantation as a means of therapy for different organ systems. However, lack of good immunosuppression and the ability to monitor and control rejection, as well as a severe organ donor shortage, opened the door for other alternatives.

As times evolved, synthetic materials were introduced to replace or rebuild diseased tissues or parts in the human body. The advent of new manmade materials, such as tetrafluoroethylene (Teflon) and silicone, opened a new field that included a wide array of devices that could be applied for human use. Although these devices could provide for structural replacement, the functional component of the original tissue was not achieved.

Simultaneous with this development was an increased body of knowledge of the biologic sciences that included new techniques for cell harvesting, culture, and expansion. The areas of cell biology, molecular biology, and biochemistry were advancing rapidly. Studies of the extracellular matrix (ECM) and its interaction with cells and with growth factors and their ligands led the way to a further understanding of cell and tissue growth and differentiation. The concept of cell transplantation took hold in the research arena and culminated with the first human bone marrow cell transplant in the 1970s.

In the 1970s, a natural evolution occurred wherein researchers started to combine the fields of devices and materials sciences with cell biology, in effect starting a new field called *tissue engineering*. As more scientists from different fields came together with the common goal of tissue replacement, the field of tissue engineering became more formally established. Tissue engineering was defined as “an interdisciplinary field which applies the principles of engineering and life sciences towards the development of biological substitutes that aim to maintain, restore or improve tissue function” (Atala and Lanza, 2001). The first use of the term *tissue engineering* in the literature can be traced to a reference dealing with corneal tissue in 1985 (Wolter et al, 1985).

The field of stem cells also received a large boost with the discovery of mouse embryonic stem cells in the early 1980s (Martin, 1981). However, the field remained relatively dormant until the description of human embryonic stem cells (hESCs) in 1998 (Thomson et al, 1998). The description of these cells led to one of the most contested ethical debates in the field of medicine. Just a year later, in 1999, the world awoke to the startling media announcement of the creation of the first cloned mammal, a sheep named Dolly (Wilmut et al, 1997). Although cloning, or nuclear transfer, had been done in amphibians and other animal models for years, this accomplishment in a mammal showed once again that concepts believed to be scientifically prohibitive were indeed possible.

The fields of cell transplantation, tissue engineering and nuclear transfer all had one unifying concept—the regeneration of living tissues (organs). Thus in 1999, William Haseltine, then the Scientific Founder and Chief Executive Officer of Human Genome Sciences, coined the term *regenerative medicine*, in effect bringing all these areas under one defining field (Haseltine, 1999). Soon the first online journal in the field, *Regenerative Medicine*, was founded, along with the Regenerative Medicine Society.

Organ transplantation remains a mainstay of treatment for patients with severely compromised organ function. Despite initiatives to increase the availability of transplant organs, however, the number of patients in need of treatment far exceeds the organ supply, and this shortfall is expected to worsen as the global population ages. One alternative treatment approach is regenerative medicine. In the last two decades, scientists have attempted to grow native and stem cells, engineer tissues, and design treatment modalities using regenerative medicine techniques for virtually every tissue of the human body. This chapter reviews some of the progress that has been achieved in the field of genitourinary regenerative medicine.

REGENERATIVE MEDICINE: STRATEGIES FOR TISSUE AND ORGAN RECONSTITUTION

Regenerative medicine follows the principles of cell transplantation, materials science, and engineering toward the development of biologic strategies that can restore and maintain normal function. Regenerative medicine strategies usually fall into one of three categories: cell-based therapies; the use of biomaterials (scaffolds) alone, wherein the body's natural ability to regenerate is used to orient or direct new tissue growth; and the use of scaffolds seeded with cells to create tissue substitutes.

SOURCES OF CELLS FOR THERAPY

Stem Cells

The cells used for regenerative medicine can be autologous or heterologous, and from either native or stem cell sources. In general, there are three broad categories of stem cells obtained from living tissue that are used for cell therapies. Embryonic stem cells are obtained through the aspiration of the inner cell mass of a blastocyst or a single cell from this mass. Fetal and neonatal amniotic fluid and placenta may contain multipotent cells that may be useful in cell therapy applications. Cord blood cells have potency mainly limited to hematopoietic lineages, although differentiation to other cell types has also been reported. Adult stem cells, on the other hand, are usually isolated from organ or bone marrow biopsy specimens. Stem cells are defined as having three important properties: the ability to self-renew, the ability to differentiate into a number of different cell types, and the ability to easily form clonal populations (populations of cells derived from a single stem cell). Many techniques for generating stem cells have been studied over the past

TABLE 20-1 Summary of Alternate Methods for Generating Pluripotent Stem Cells

METHOD	ADVANTAGES	LIMITATIONS
Somatic cell nuclear transfer	Customized stem cells Has been shown to work in nonhuman primates	Requires oocytes Has not been shown to work in humans
Single-cell embryo biopsy	Patient specific to embryo Does not destroy or create embryos Has been done in humans	Allogeneic cell types Is not known if single cells are totipotent Requires coculturing with a previously established human embryonic stem cell line
Arrested embryos	Cells obtained from discarded embryos Has been done in humans	Allogeneic cell types Quality of cell lines might be questionable
Altered nuclear transfer	Customized stem cells	Ethical issues surround embryos with no potential Modified genome Has not been done with human cells
Reprogramming	Customized stem cells No embryos or oocytes needed Has been done with human cells	Retroviral transduction Oncogenes

few decades. Some of these techniques have yielded promising results, but others require further research. The main techniques are discussed in detail later, and their advantages and limitations are summarized in [Table 20-1](#).

Embryonic Stem Cells

In 1981 pluripotent cells were found in the inner cell mass of the human embryo, and the term *human embryonic stem cell* was coined ([Martin, 1981](#)). These cells are able to differentiate into all cells of the human body, excluding placental cells (only cells from the morula are totipotent—that is, able to develop into all cells of the human body). These cells have great therapeutic potential; their use is limited mostly by their biologic properties.

An ethical controversy surrounding stem cells was initiated in 1998 with the creation of hESCs derived from discarded embryos. hESCs were isolated from the inner cell mass of a blastocyst (an embryo 5 days after fertilization) using an immunosurgical technique. Given that some cells cannot be expanded *ex vivo*, hESCs could be an ideal resource for regenerative medicine because of their fundamental properties: the ability to self-renew indefinitely and the ability to differentiate into cells from all three embryonic germ layers, from skin to neurons. In addition, as further evidence of their pluripotency, embryonic stem cells can form embryoid bodies, which are cell aggregations that contain all three embryonic germ layers while in culture, and can form teratomas *in vivo* ([Itskovitz-Eldor et al, 2000](#)). These cells have demonstrated longevity in culture and can maintain their undifferentiated state for at least 80 passages when grown using current published protocols ([Thomson et al, 1998](#)). However, the clinical application of

embryonic stem cells is limited because they represent an allogeneic resource and thus have the potential to evoke an immune response. In addition, by definition the cells form teratomas, which may be problematic when treating patients. In October 2010, a phase 1 clinical trial was begun to assess the safety of hESC-derived oligodendrocyte progenitors for patients with thoracic spinal cord injuries. Unfortunately, the trial was discontinued in November 2011 ([Frantz, 2012](#)). hESC-derived retinal pigment epithelium has also been used in patients with macular degeneration and dystrophy ([Schwartz et al, 2012](#)). It might seem that we have waited too long to see hESCs in the clinic. However, this has been accomplished with incredible speed when it is considered that hESCs were first isolated just in 1998 ([Atala, 2012](#)).

A major objection to hESC research by some is that it results in the destruction of embryos. A method of isolating these cells without destroying the embryo would be advantageous. Three methods have been established experimentally for the generation of embryonic stem cell lines using alternate techniques whereby the embryos are not destroyed; these include performing a single-cell embryo biopsy ([Chung et al, 2006](#)), obtaining cells from arrested embryos ([Zhang et al, 2006a](#)), and using altered nuclear transfer ([Hurlbut, 2005](#); [Meissner and Jaenisch, 2006](#)).

A description of these techniques appears on the Expert Consult website.

Therapeutic Cloning (Somatic Cell Nuclear Transfer)

SCNT, or therapeutic cloning, entails the removal of an oocyte nucleus in culture, followed by its replacement with a nucleus derived from a somatic cell obtained from a patient. Activation with chemicals or electricity stimulates cell division up to the blastocyst stage.

It is important to differentiate between the two types of cloning that exist—reproductive cloning and therapeutic cloning. Both involve the insertion of donor DNA into an enucleated oocyte to generate an embryo that has identical genetic material to its DNA source. However, the similarities end there. In reproductive cloning, the embryo is implanted into the uterus of a pseudopregnant female to produce an infant that is a clone of the donor. A prominent example of this type of cloning resulted in the birth of a sheep named Dolly in 1997 ([Wilmut et al, 1997](#)). However, there are many ethical concerns surrounding such practices, and as a result, reproductive cloning has been banned.

Although therapeutic cloning also produces an embryo that is genetically identical to the donor, this process is used to generate blastocysts that are explanted and grown in culture rather than *in utero*. Embryonic stem cell lines can then be derived from blastocysts, which are allowed to grow only up to a 100-cell stage. At this time the inner cell mass is isolated and cultured, resulting in embryonic stem cells that are genetically identical to the patient. This process is detailed in [Figure 20-1](#). It has been shown that nuclear-transferred embryonic stem cells derived from fibroblasts, lymphocytes, and olfactory neurons are pluripotent and can generate live pups after injection into blastocysts. This shows that cells generated by SCNT have the same developmental potential as blastocysts that are fertilized and produced naturally ([Hochedlinger et al, 2002](#); [Eggan et al, 2004](#); [Brambrink et al, 2006](#)). In addition, the embryonic stem cells generated by SCNT are perfectly matched to the patient's immune system and no immunosuppressants would be required to prevent rejection should these cells be used in regenerative medicine applications.

Although embryonic stem cells derived from SCNT contain the nuclear genome of the donor cells, mitochondrial DNA (mtDNA) contained in the oocyte could lead to immunogenicity after transplantation. To assess the histocompatibility of tissue generated using SCNT, the nucleus of a bovine skin fibroblast was microinjected into an enucleated oocyte ([Lanza et al, 2002](#)). Although the blastocyst was implanted (reproductive cloning), the purpose was to generate renal, cardiac, and skeletal muscle cells, which were then harvested, expanded *in vitro*, and seeded onto biodegradable scaffolds. These scaffolds were then implanted into the donor steer

SOURCES OF CELL THERAPY: STEM CELLS

Single-Cell Embryo Biopsy

In 2006, Chung and colleagues were the first authors to report the generation of mouse embryonic stem cell lines via single-cell embryo biopsy (Chung et al, 2006). Their method was based on a technique used to obtain a single-cell embryo biopsy specimen for preimplantation genetic diagnosis. Cells were taken from eight-cell blastomeres rather than from blastocysts. The cells differentiated into derivatives of all three embryonic germ layers in vitro and as well as into teratomas in vivo. In addition, the mouse embryos that resulted from the biopsied blastomeres developed to term without a reduction in their developmental potential.

Obtaining Cells from Arrested Embryos

hESC lines can also be derived from arrested embryos. (Zhang et al, 2006a). During in vitro fertilization, only a small proportion of zygotes produced will develop successfully to the morula and blastocyst stages. Over half the embryos stop dividing (Hardy, 1993; Geber and Sampaio, 1999) and are therefore considered dead embryos (Landry and Zucker, 2004). Such embryos have unequal or fragmented cells and blastomeres and are usually discarded. Not all the cells within these arrested embryos, however, are abnormal (Martinez et al, 2002; Zhang et al, 2006a), and these embryos might be a source of hESCs. More studies are needed to characterize the full proliferation and differentiation potential of embryonic stem cells derived from arrested embryos.

Altered Nuclear Transfer

Altered nuclear transfer is a variation of somatic cell nuclear transfer (SCNT) in which a genetically modified nucleus from a somatic cell is transferred into a human oocyte. This embryo, which contains a deliberate genetic defect, is capable of developing into a blastocyst, but the induced defect prevents the blastocyst from implanting in the uterus. This process has the potential to generate customized hESCs from the blastocyst stage (Hurlbut, 2005). Human embryos with this genetic defect might lack the capacity to develop into viable fetuses as a result of their inability to implant, thus providing a source of stem cells without the destruction of viable embryos. Proof of concept was obtained in mice by Meissner and Jaenisch in 2006 using embryos lacking the *Cdx2* homeobox gene (Meissner and Jaenisch, 2006).

The viability of human embryos lacking the *CDX2* gene is unclear, as is whether this mutation restricts human developmental potential into certain lineages. Although much research must be done before therapeutic strategies based on this technique could ever enter the clinic, at this time hESCs derived from altered nuclear transfer can provide opportunities to study pluripotency in hESCs without the need for destruction of viable embryos. The exact effects of *CDX2* gene knockout on the development of human embryos are not well known. The effects of this gene, however, have been thoroughly investigated in the gastric and intestinal epithelium (Benahmed et al, 2008; Vauhkonen et al, 2008).

Figure 20-1. Therapeutic cloning strategy and its application to the engineering of tissues and organs.

from which the cells were cloned to determine if the cells were histocompatible. Analysis revealed that cloned renal cells showed no evidence of T-cell response, suggesting that rejection will not necessarily occur in the presence of oocyte-derived mtDNA. This finding represents a step forward in overcoming the histocompatibility problem of stem cell therapy.

Although promising, SCNT has certain limitations that require further improvement before its clinical application, in addition to the ethical considerations regarding the potential of the resulting embryos to develop into cloned embryos if implanted into a uterus. In addition, this technique has not been shown to work in humans to date. The initial failures and fraudulent reports of nuclear transfer in humans reduced enthusiasm for human applications (Simerly et al, 2003; Hwang et al, 2004, 2005), although nonhuman primate embryonic stem cell lines have been generated by SCNT of nuclei from adult skin fibroblasts (Byrne et al, 2007; Mitalipov, 2007).

Reprogramming (Induced Pluripotent Stem Cells)

Reprogramming is a technique that involves de-differentiation of adult somatic cells to produce patient-specific pluripotent stem cells, eliminating the need to create embryos. Cells generated by reprogramming would be genetically identical to the somatic cells (and therefore to the patient who donated these cells) and would not be rejected. Yamanaka was the first to discover that mouse embryonic fibroblasts (MEFs) and adult mouse fibroblasts could be reprogrammed into an “induced pluripotent state (iPS)” (Takahashi et al, 2006). These iPS cells possessed the immortal growth characteristics of self-renewing embryonic stem cells, expressed genes specific for embryonic stem cells, and generated embryoid bodies in vitro and teratomas in vivo. When iPS cells were injected into mouse blastocysts, they contributed to a variety of cell types. However, although iPS cells selected in this way were pluripotent, they were not identical to embryonic stem cells. Unlike with embryonic stem cells, chimeras made from iPS cells did not result in full-term pregnancies. Gene expression profiles of the iPS cells showed that they possessed a distinct gene expression signature that was different from that of embryonic stem cells. In addition, the epigenetic state of the iPS cells was somewhere between that found in somatic cells and that found in embryonic stem cells, suggesting that the reprogramming was incomplete.

These results were improved by Wernig and Jaenisch in July 2007 (Wernig et al, 2007). In this study, DNA methylation, gene expression profiles, and the chromatin state of the reprogrammed cells were similar to those of embryonic stem cells. Teratomas induced by these cells contained differentiated cell types representing all

three embryonic germ layers. Most important, the reprogrammed cells from this experiment were able to form viable chimeras and contribute to the germline-like embryonic stem cells, suggesting that these iPS cells were completely reprogrammed.

A major advance has been the reprogramming of human cells (Takahashi et al, 2007; Yu et al, 2007). Yamanaka generated human iPS cells that are similar to hESCs in terms of morphology, proliferation, gene expression, surface markers, and teratoma formation. Yamanaka received the Nobel Prize in Medicine for this work in 2012. Thompson’s group showed that retroviral transduction of the stem cell markers *OCT4*, *SOX2*, *NANOG*, and *LIN28* could generate pluripotent stem cells. Recently the cells have been noted to have the potential to be reversed to a ground state of pluripotency (Gafni et al, 2013). Since the discovery of iPS cells, work surrounding these cells has grown exponentially, with more than 6000 peer-reviewed papers listed in MEDLINE by 2014. The cells have shown great promise in the understanding of human disease, as well as the use of these cells for therapy. Like embryonic stem cells, the iPS cells also form teratomas, and this has limited their therapeutic potential, with no human trials to date. Direct in vivo reprogramming also leads to the formation of teratomas (Abad et al, 2013). Nonetheless, the potential of reprogramming remains exciting.

Perinatal Stem Cells

Various sources of perinatal stem cells have been reported, with varied potency. Umbilical cord blood is collected at the time of birth and provides a source of undifferentiated cells that may be banked at the time of birth to be available for autologous and allogeneic cell therapy. Umbilical cord blood stem cells were first used clinically in 1989 (Gluckman et al, 1989). Since then, the cells have been used in more than 25,000 patients worldwide. The cells are more immature than adult bone marrow stem cells (Tursky et al, 2012). Cord blood stem cells are mostly used for hematopoietic applications (Kurtzberg, 1996).

Early stem cell populations can be obtained from Wharton jelly, which surrounds the cord (Romanov et al, 2003; Hass et al, 2011). The cells are mesenchymal in origin, although limited multipotentiality has been demonstrated. The cells have not been used clinically.

The most recent perinatal stem cell type described was derived from both the amniotic fluid and placenta. The isolation of multipotent human and mouse amniotic fluid and placental-derived stem (AFPS) cells that are capable of extensive self-renewal and give rise to cells from all three germ layers was reported in 2007 (De Coppi et al, 2007b). AFPS cells represent a class of stem cells with

properties somewhere between those of embryonic and adult stem cell types; they are more agile than adult stem cells but less so than embryonic stem cells. Unlike embryonic and induced pluripotent stem cells, however, AFPS cells do not form teratomas, and if preserved for self-use, avoid the problems of rejection. The cells could be obtained either from amniocentesis or chorionic villous sampling in the developing fetus or from the placenta at the time of birth. The cells can be directed into all three germ layers, and they expand readily. Amniotic fluid stem cells have been used experimentally to treat bladder dysfunction (De Coppi et al, 2007a). Many different stem cell types can be obtained from the amniotic fluid or the placenta. There are more than 2500 references in the literature to studies involving these cells. The cells have varied properties and applications, depending on the specific source (Murphy and Atala, 2013).

Adult Stem Cells

Adult stem cells, especially hematopoietic stem cells from the bone marrow, are the best understood cell type in stem cell biology (Ballas et al, 2002). These cells have been used for decades for hematopoietic disorders. However, adult stem cell research remains an area of intense study, as the potential of these cells for therapy may be applicable to myriad degenerative disorders. Within the past decade, adult stem cell populations have been found in many adult tissues other than the bone marrow and the gastrointestinal tract, including the brain (Taupin, 2006; Jiao et al, 2008), skin (Jensen et al, 2008), and muscle (Crisan et al, 2008). Many types of adult stem cells have been identified in organs throughout the body and are thought to serve as the primary repair entities for their corresponding organs (Weiner, 2008) (Fig. 20-2). The discovery of such tissue-specific progenitors has opened up new avenues for research.

A notable exception to the tissue specificity of adult stem cells is the mesenchymal stem cell, also known as the *multipotent adult progenitor cell*. This cell type is also derived from bone marrow stroma (Devine, 2002; Jiang et al, 2002). Such cells can differentiate in vitro into numerous tissue types (Caplan, 2007; da Silva Meirelles et al, 2008). Some cells, such as those of the liver, pancreas, and nerve, have very low proliferative capacity in vitro, and the functionality of some cell types is reduced after the cells are cultivated. Isolation of cells has also been problematic because stem cells are present in extremely low numbers in adult tissue (Hristov et al, 2008; Mimeault et al, 2008). Bone marrow stem cells have been differentiated to both bladder urothelium and muscle (Anumanthan et al, 2008; Tian et al, 2010). The cells have also been used in experimental animal models for the enhancement of bladder function and regeneration (Soler et al, 2012; Sharma et al, 2013).

Figure 20-2. Schematic diagram of pluripotential stem cell lineages that can be derived from postnatal tissue.

Adipose-derived stem cells that could give rise to multiple lineages were first reported in 2001 (Zuk et al, 2001). The cells have been used for differentiation into urologic cells such as bladder smooth muscle (Jack et al, 2009; Zhang et al, 2012b) and urothelium (Zhang et al, 2013). The adipose-derived cells have also been used experimentally to improve bladder function (Zhang et al, 2012a; Song et al, 2013). Urine-derived stem cells have also been proposed for genitourinary reconstruction (Zhang et al, 2008; Bharadwaj et al, 2013).

Although the clinical usefulness of adult stem cells is currently limited, great potential exists for future use of such cells in tissue-specific regenerative therapies. The advantage of adult stem cells is that they can be used in autologous therapies, thus avoiding any complications associated with immune rejection. Composite adult cell populations from many sources, including bone marrow, fat, and fragments of peripheral blood have been used more extensively in patients for multiple indications more recently. These cells are currently being tested for urologic applications, such as erectile or voiding dysfunction. The mechanisms behind their mode of action need to be further elucidated.

Native Targeted Progenitor Cells

In the past, one of the limitations of applying cell-based regenerative medicine techniques to organ replacement was the inherent difficulty of growing certain human cell types in large quantities. Native targeted progenitor cells, or native cells, are tissue specific unipotent cells derived from most organs. The advantage of these cells is that they are already programmed to become the cell type needed, without any extra-lineage differentiation. By noting the location of the progenitor cells, as well as by exploring the conditions that promote differentiation and/or self-renewal, it has been possible to overcome some of the obstacles that limit cell expansion in vitro. One example is the urothelial cell. Urothelial cells could be grown in the laboratory setting in the past, but only with limited success. It was believed that urothelial cells had a natural senescence that was hard to overcome. Several protocols have been developed over the last two decades that have improved urothelial growth and expansion (Cilento et al, 1994; Liebert et al, 1997; Scriven et al, 1997; Puthenveetil et al, 1999). A system of urothelial cell harvesting was developed that does not use any enzymes or serum and has a large expansion potential. Using these methods of cell culture, it is possible to expand a urothelial strain from a single specimen that initially covers a surface area of 1 cm² to one covering a surface area of 4202 m² (the equivalent area of one football field) within 8 weeks (Cilento et al, 1994).

An additional advantage in using native cells is that they can be obtained from the specific organ to be regenerated, expanded, and used in the same patient without rejection, in an autologous manner. Bladder, ureter, and renal pelvis cells can equally be harvested, cultured, and expanded in a similar fashion. Normal human bladder epithelial and muscle cells can be efficiently harvested from surgical material and extensively expanded in culture, and their differentiation characteristics, growth requirements, and other biologic properties can be studied (Liebert et al, 1991; Cilento et al, 1994; Tobin et al, 1994; Harriss, 1995; Freeman et al, 1997; Liebert et al, 1997; Fauza et al, 1998; Lobban et al, 1998; Solomon et al, 1998; Nguyen et al, 1999; Puthenveetil et al, 1999; Rackley et al, 1999). Major advances in cell culture techniques have been made within the past several decades, and these techniques make the use of autologous cells possible for clinical application. However, even now, not all human cells can be grown or expanded in vitro. Liver, nerve, and pancreas are examples of human tissues for which the technology is not yet advanced to the point where these cells can be grown and expanded.

When cells are used for tissue reconstitution, donor tissue is dissociated into individual cells, which are either implanted directly into the host or expanded in culture, attached to a support matrix, and reimplanted after expansion.

BIOMATERIALS AND VASCULARIZATION FOR GENITOURINARY REGENERATIVE MEDICINE

For regenerative medicine purposes, there are clear advantages to use of degradable, biocompatible materials that can function as cell delivery vehicles and/or provide the structural parameters needed for tissue replacement. **Biomaterials in regenerative medicine function as an artificial ECM and elicit biologic and mechanical functions of native ECM found in tissues in the body.** Native ECM brings cells together into tissue, controls the tissue structure, and regulates the cell phenotype (Alberts et al, 1994). Biomaterials facilitate the localization and delivery of cells and/or bioactive factors (e.g., cell adhesion peptides, growth factors) to desired sites in the body; define a three-dimensional space for the formation of new tissues with appropriate structure; and guide the development of new tissues with appropriate function (Kim et al, 1998). Direct injection of cell suspensions without biomaterial matrices has been used in some cases (Ponder et al, 1991; Brittberg et al, 1994), but it is difficult to control the localization of transplanted cells. In addition, the majority of mammalian cell types are anchorage dependent and will die if not provided with a cell-adhesion substrate.

Design and Selection of Biomaterials

The design and selection of the biomaterial is critical in the development of engineered genitourinary tissues. The biomaterial must be capable of controlling the structure and function of the engineered tissue in a predesigned manner by interacting with transplanted cells and/or host cells. In general, the ideal biomaterial should be biocompatible, promote cellular interaction and tissue development, and possess proper mechanical and physical properties.

The selected biomaterial should be biodegradable and biore-sorbable to support the reconstruction of a completely normal tissue without inflammation. Such behavior of the biomaterials avoids the risk of inflammatory or foreign-body responses that may be associated with the permanent presence of a foreign material in the body. The degradation rate and the concentration of degradation products in the tissues surrounding the implant must be at a tolerable level (Bergsma et al, 1995).

The biomaterials should provide an appropriate regulation of cell behavior (e.g., adhesion, proliferation, migration, differentiation) to promote the development of functional new tissue. Cell behavior in engineered tissues is regulated by multiple interactions with the microenvironment, including interactions with cell-adhesion ligands (Hynes, 1992) and with soluble growth factors (Deuel, 1997). Cell adhesion-promoting factors (e.g., Arg-Gly-Asp [RGD]) can be presented by the biomaterial itself or incorporated into the biomaterial to control cell behavior through ligand-induced cell receptor signaling processes (Barrera et al, 1993; Cook et al, 1997). The biomaterials provide temporary mechanical support sufficient to withstand in vivo forces exerted by the surrounding tissue and maintain a potential space for tissue development. The mechanical support of the biomaterials should be maintained until the engineered tissue has sufficient mechanical integrity to support itself (Atala, 2007). This potentially can be achieved by an appropriate choice of mechanical and degradative properties of the biomaterials (Kim et al, 1998).

The biomaterials need to be processed into specific configurations. A large ratio of surface area to volume is often desirable to allow the delivery of a high density of cells. A high-porosity, interconnected pore structure with specific pore sizes promotes tissue ingrowth from the surrounding host tissue. Several techniques, such as electrospinning, have been developed that readily control porosity, pore size, and pore structure (Lee et al, 2007; Yoo et al, 2007; Choi et al, 2008; Lee et al, 2008a, 2008b, 2008c, 2010).

In general, three classes of biomaterials have been used for engineering of genitourinary tissues: naturally derived materials, such as collagen; acellular tissue matrices, such as bladder submucosa and small-intestinal submucosa; and synthetic polymers,

such as polyglycolic acid (PGA), polylactic acid (PLA), and poly(lactic-co-glycolic acid) (PLGA). These classes of biomaterials have been tested with regard to their biocompatibility with primary human urothelial and bladder muscle cells (Pariente et al, 2001). Naturally derived materials and acellular tissue matrices have the potential advantage of biologic recognition. Synthetic polymers can be produced reproducibly on a large scale with controlled properties of strength, degradation rate, and microstructure. Combination scaffolds have also been used (Engelhardt et al, 2011).

Additional information on the general types of biomaterials used can be found on the Expert Consult website.

Vascularization

The goals in regenerative medicine include the replacement of damaged, injured, or missing body tissues with biologic-compatible substitutes. **A limiting factor for the engineering of tissues is that cells cannot be implanted in volumes exceeding 3 mm³ (Folkman and Hochberg, 1973).** Nutrition and gas exchange are limited by this maximal diffusion distance. If cells were implanted in volumes exceeding 3 mm³, only the cells on the surface would survive, and the central cell core would undergo necrosis resulting from a lack of vascularity. Therefore a critical obstacle in regenerative medicine is the ability to maintain large masses of cells alive, on transfer from the in vitro culture conditions into the host, in vivo (Mooney and Mikos, 1999). To achieve the goals of engineering large complex tissues, and possibly internal organs, vascularization of the regenerating cells is essential.

Formation of new blood vessels and capillaries is composed of two different processes: vasculogenesis, the in situ assembly of capillaries from undifferentiated endothelial cells (ECs), and angiogenesis, the sprouting of capillaries from preexisting blood vessels.

More information on these two processes is included on the Expert Consult website.

The understanding of the angiogenic process and the isolation of potent and specific angiogenic growth factors has encouraged the use of these factors therapeutically (Loges et al, 2009; Phelps and Garcia, 2009). Efforts have been aimed at incorporating the knowledge acquired in angiogenesis of ischemic tissues into practical approaches to vascularize bioengineered tissues (Stosich et al, 2009). Bioengineered tissues are usually supported by scaffolds of biocompatible matrices made from natural or artificial sources (Hubbell et al, 1991). Successful vascularization is dependent on the porosity of the supporting matrix. A positive correlation between the pore size of poly(L-lactic acid) (PLLA) implants and the rate of vascularization has been observed (Mikos et al, 1993).

Three approaches have been used for vascularization of bioengineered tissue: (1) incorporation of angiogenic factors in the bioengineered tissue; (2) seeding ECs with other cell types in the bioengineered tissue; and (3) prevascularization of the matrix before cell seeding. Angiogenic growth factors may be incorporated into the bioengineered tissue before implantation, to attract host capillaries and to enhance neovascularization of the implanted tissue. Angiogenic growth factors can be embedded in specific biomaterials and can be controlled to be released slowly (Eiselt et al, 1998). Cells can also be genetically engineered to secrete high levels of angiogenic proteins (Springer et al, 1998).

Another approach for enhancing angiogenesis employed cultured ECs, which are incorporated into the bioengineered tissue before implantation. Human penile corpus cavernosum-derived smooth muscle cells and ECs were seeded on biodegradable polymer scaffolds to reconstruct penile corporeal tissue in vitro and in vivo (Park et al, 1999). The use of ECs improved the formation of the engineered tissue. In another study the addition of both ECs and angiogenic growth factors (VEGF) accelerated the formation of engineered muscle tissue (De Coppi et al, 2005). An alternative direction in vascularization of bioengineered tissue is the prevascularization of the supporting polymer before cell seeding. In this manner, the bioengineered tissue will be organized around the vascular network, providing sufficient tissue perfusion (Fontaine et al, 1995).

Types of Biomaterials

Collagen is the most abundant and ubiquitous structural protein in the body, and it may be readily purified from both animal and human tissues with an enzyme treatment and salt and acid extraction (Li, 1995). Collagen has long been known to exhibit minimal inflammatory and antigenic responses (Furthmayr and Timpl, 1976), and it has been approved by the U.S. Food and Drug Administration (FDA) for many types of medical applications, including wound dressings and artificial skin (Cen et al, 2008). Intermolecular cross-linking reduces the degradation rate by making the collagen molecules less susceptible to an enzymatic attack. Intermolecular cross-linking can be accomplished by various physical (e.g., ultraviolet radiation, dehydrothermal treatment) or chemical (e.g., glutaraldehyde, formaldehyde, carbodiimides) techniques (Li, 1995). Collagen contains cell-adhesion domain sequences (e.g., RGD) that exhibit specific cellular interactions. This may help to retain the phenotype and activity of many types of cells, including fibroblasts (Silver et al, 1992) and chondrocytes (Sams and Nixon, 1995). This material can be processed into a wide variety of structures such as sponges (Fig. 20-3A), fibers, and films (Yannas et al, 1980a, 1980b; Cavallaro et al, 1994).

Figure 20-3. Scanning electron micrographs of biomaterials: collagen sponge (A), acellular matrix prepared from pig bladder submucosa (B), and polyglycolic acid fiber-based matrix (C). (Size bars = 100 μ m.)

Alginate, a polysaccharide isolated from seaweed, has been used as an injectable cell delivery vehicle (Smidsrod et al, 1990) and a cell immobilization matrix (Lim and Sun, 1980) owing to its gentle gelling properties in the presence of divalent ions such as calcium. Alginate is a family of copolymers of D-mannuronate and L-guluronate. The physical and mechanical properties of alginate gel are strongly correlated with the proportion and length of the polyguluronate block in the alginate chains (Smidsrod et al, 1990). Efforts have been made to synthesize biodegradable alginate hydrogels with mechanical properties that are controllable in a wide range by intermolecular covalent cross-linking and with cell-adhesion peptides coupled to their backbones (Rowley et al, 1999).

Natural materials such as alginate and collagen have been used as “bio-inks” in a newly developed bioprinting technique based on inkjet technology (Boland et al, 2006; Campbell and Weiss, 2007; Skardal et al, 2012; Murphy et al, 2013). With this technology, these scaffold materials can be “printed” into a desired scaffold shape using a modified inkjet printer. In addition, several groups have shown that living cells can also be printed using this technology (Lafamme et al, 2005; Xu et al, 2013). This exciting technique can be modified so that a three-dimensional construct containing a precise arrangement of cells, growth factors, and ECM material can be printed (Roth et al, 2004; Ilkhanizadeh et al, 2007; Xu et al, 2009). The bioprinting technology is currently being used to print several urologic structures, including miniature kidneys.

Acellular tissue matrices are collagen-rich matrices prepared by removing cellular components from tissues (Fig. 20-3B). The matrices are often prepared by mechanical and chemical manipulation of a segment of bladder tissue (Dahms et al, 1998; Piechota et al, 1998; Yoo et al, 1998b; Chen et al, 1999). The matrices slowly degrade after implantation and are replaced and remodeled by ECM proteins synthesized and secreted by transplanted or ingrowing cells. Acellular tissue matrices have been proved to support cell ingrowth and regeneration of genitourinary tissues, including urethra and bladder, with no evidence of immunogenic rejection (Probst et al, 1997; Chen et al, 1999). Because the structures of the proteins (e.g., collagen, elastin) in acellular matrices are well conserved and normally arranged, the mechanical properties of the acellular matrices are not significantly different from those of native bladder submucosa (Dahms et al, 1998).

Polyesters of naturally occurring α -hydroxy acids, including PGA, PLA, and PLGA, are widely used in regenerative medicine. These polymers have gained FDA approval for human use in a variety of applications, including sutures (Gilding, 1981). The degradation products of PGA, PLA, and PLGA are nontoxic, natural metabolites that are eventually eliminated from the body in the form of carbon dioxide and water (Gilding, 1981). Because these polymers are thermoplastics, they can easily be formed into a three-dimensional scaffold with a desired microstructure, gross shape, and dimension by various techniques, including molding, extrusion (Freed et al, 1994), solvent casting (Mikos et al, 1994), phase separation techniques, and gas foaming techniques (Harris et al, 1998). More recently, techniques such as electrospinning have been used to quickly create highly porous scaffolds in various conformations (Han et al, 2006; Choi et al, 2008; Lee et al, 2008a, 2008b).

Many applications in genitourinary regenerative medicine require a scaffold with high porosity and a high ratio of surface area to volume. This need has been addressed by processing biomaterials into configurations of fiber meshes (Fig. 20-3C) and porous sponges using the techniques described previously. A drawback of the synthetic polymers is lack of biologic recognition. As an approach toward incorporating cell recognition domains into these materials, copolymers with amino acids have been synthesized (Barrera et al, 1993; Intveld et al, 1994; Cook et al, 1997). Other biodegradable synthetic polymers, including poly(anhydrides) and poly(orthoesters), can also be used to fabricate scaffolds for genitourinary regenerative medicine with controlled properties (Peppas et al, 1994).

Nanotechnology, the ability to use small molecules that have distinct properties in a small scale, has been used to create “smart” biomaterials for regenerative medicine ([Boccaccini et al, 2005](#); [Harrison et al, 2007](#)). Nanoscaffolds have been manufactured specifically for bladder applications ([Harrington et al, 2006](#)). The manufacturing of biomaterials can also lead to enhanced cell alignment and tissue formation ([Choi et al, 2008](#)).

Vascularization for Genitourinary Regenerative Medicine

The formation of the first capillaries takes place mostly during the early stages of embryogenesis (Folkman and D'Amore, 1996; Yancopoulos et al, 1998). Vasculogenesis can be divided into five consecutive steps: (1) ECs are generated from precursor cells, called *angioblasts*, in the bone marrow; (2) ECs form the vessel primordia and aggregates, which establish cell-to-cell contact but have no lumen; (3) a nascent endothelial tube is formed, composed of polarized ECs; (4) a primary vascular network is formed from an array of nascent endothelial tubes; and (5) pericytes and vascular smooth muscle cells are recruited (Drake et al, 1998).

Angiogenesis is a morphogenic process—new blood capillaries are formed from ECs of preexisting vessels. There are six basic steps in angiogenesis: (1) vasodilatation of the parental vessel, reducing the contact between adjacent ECs; (2) degradation of

the basement membrane of a parental vessel by secretion and activation of a wide range of proteolytic enzymes; (3) EC migration and proliferation to form a leading edge of the new capillary; (4) generation of the capillary lumen and formation of a tubelike structure; (5) basement membrane synthesis; and (6) recruitment of pericytes and vascular smooth muscle cells (Folkman and Brem, 1992).

When converting to the angiogenic stage, ECs capture new properties that enable them to neovascularize the tissue (Hanahan and Folkman, 1996). When the new vessels are in place and the vascular network matures, the neovascular ECs resume their quiescent phenotype (Darland and D'Amore, 1999). Several growth factors serve as stimuli for EC conversion to the angiogenic phenotype (Battegay, 1995). Vascular endothelial growth factor (VEGF) and fibroblast growth factor (FGF) are two well characterized and important angiogenic molecules that have a direct effect on ECs.

Despite the successes in bioengineering tissues consisting of thin layers of cells such as skin, a major challenge for regenerative medicine in the future is the production of larger organs with more complex structures, such as the kidney. Tissues with a large mass of cells require a vascular network of arteries, veins, and capillaries to deliver nutrients to each cell. The development of efficient methods to vascularize bioengineered tissues is critical for a successful outcome. There are many obstacles to overcome before large entire tissue-engineered solid organs are produced. Recent developments in angiogenesis research may provide important knowledge and are essential.

REGENERATIVE MEDICINE OF UROLOGIC STRUCTURES

Urethra

Various strategies have been proposed over the years for the regeneration of urethral tissue. Woven meshes of PGA without cells (Bazeed et al, 1983; Olsen et al, 1992) and with cells (Atala, et al, 1992) were used to regenerate urethras in various animal models. Naturally derived collagen-based materials such as bladder-derived acellular submucosa (Chen et al, 1999), acellular urethral submucosa (Sievert et al, 2000), and collagen gels (Micol et al, 2012) have also been tried experimentally in various animal models for urethral reconstruction.

The bladder submucosa matrix (Chen et al, 1999) proved to be a suitable graft for repair of urethral defects in rabbits. The neourethras demonstrated a normal urothelial luminal lining and organized muscle bundles. These results were confirmed clinically in a series of patients with a history of failed hypospadias reconstruction wherein the urethral defects were repaired with human bladder acellular collagen matrices (Atala et al, 1999). The neourethras were created by anastomosing the matrix in an onlay fashion to the urethral plate. The size of the created neourethra ranged from 5 to 15 cm. After a 3-year follow-up, three of the four patients had a successful outcome with regard to cosmetic appearance and function (Fig. 20-4). One patient who had a 15-cm neourethra created

Figure 20-4. Urethrogram 6 months after surgery in a patient who had a portion of his urethra replaced as an onlay with the use of an acellular bladder submucosa matrix.

developed a subglanular fistula. The acellular collagen-based matrix eliminated the necessity of performing additional surgical procedures for graft harvesting, and both operative time and the potential morbidity from the harvest procedure were decreased. Similar results were obtained in pediatric and adult patients with primary urethral stricture disease using the same collagen matrices (El-Kassaby et al, 2003). Another study in 30 patients with recurrent stricture disease showed that a healthy urethral bed (two or fewer prior urethral surgeries) was needed for successful urethral reconstruction using acellular collagen-based grafts (El-Kassaby et al, 2008). A clinical trial using tubularized nonseeded small intestinal submucosa (SIS) for urethral stricture repair was performed in eight evaluable patients. Two patients with short inflammatory strictures maintained urethral patency. Stricture recurrence developed in the other six patients within 3 months of surgery (le Roux, 2005). Many pediatric and adult patients with urethral disease have been successfully treated in an onlay manner with collagen-based matrices. One of the advantages of this method over nongenital tissue grafts used for urethroplasty is that the material is “off the shelf.” This eliminates the necessity of additional surgical procedures for graft harvesting, which may decrease operative time, as well as the potential morbidity from the harvest procedure.

The techniques previously described, involving the use of nonseeded acellular matrices, were applied experimentally and clinically in a successful manner for onlay urethral repairs. However, when tubularized urethral repairs were attempted experimentally, adequate urethral tissue regeneration was not achieved and complications ensued, such as graft contracture and stricture formation (De Filippo et al, 2002). Autologous rabbit bladder epithelial and smooth muscle cells were grown and seeded onto preconfigured tubular matrices. Entire urethra segments were resected and urethroplasties were performed with tubularized collagen matrices either seeded with cells or without cells. The tubularized collagen matrices seeded with autologous cells formed new tissue that was histologically similar to native urethra. Use of the tubularized collagen matrices without cells led to poor tissue development, fibrosis, and stricture formation (Orabi et al, 2013). These findings were confirmed clinically. In a pilot series of patients published in *The Lancet*, five patients with urethral injuries secondary to motor vehicle accidents had a small tissue biopsy specimen retrieved starting in 2004. The cells were expanded in vitro and seeded in two layers, muscle and epithelia, on tubularized scaffolds that were implanted surgically (Fig. 20-5). The tubularized engineered urethras were able to show adequate anatomy, both by urethroscopy and with urethrog-raphy (see Fig. 20-5), and function long term, currently with follow-up exceeding 10 years (Raya-Rivera et al, 2011). In another series of five patients, tissue-engineered oral mucosa was seeded in cadaveric dermis, mainly with fibroblasts and keratinocytes. All patients required instrumentation postoperatively because of strictures, but they all had the diagnosis of lichen sclerosis (Bhargava et al, 2008). Other cell types have also been tried experimentally in acellular bladder collagen matrices, including foreskin epidermal cells and oral keratinocytes (Fu et al, 2007; Li et al, 2008). VEGF gene-modified urothelial cells have also been used experimentally for urethral reconstruction (Guan et al, 2008).

The normal wound healing response to injury has been studied extensively, and this knowledge has been helpful in maximizing success for the engineering of tissues. At the time of tissue injury, cell ingrowth is initiated from the wound edges to cover the tissue defect. The cells from the edges of the native tissue are able to traverse short distances without any detrimental effects. If the wound is large, more than a few millimeters in distance or depth, increased collagen deposition, fibrosis, and scar formation ensue. Matrices implanted in wound beds are able to lengthen the distances that cells can traverse without initiating an adverse fibrotic response. However, these distances are also limited. The maximum distance that adjacent cells from the wound edge have to travel to create normal tissue over a biologic matrix is approximately 1 cm (Dorin et al, 2008). Tissue defects greater than 1 cm that are treated with a matrix alone, without cells, usually have increased collagen deposition, increased

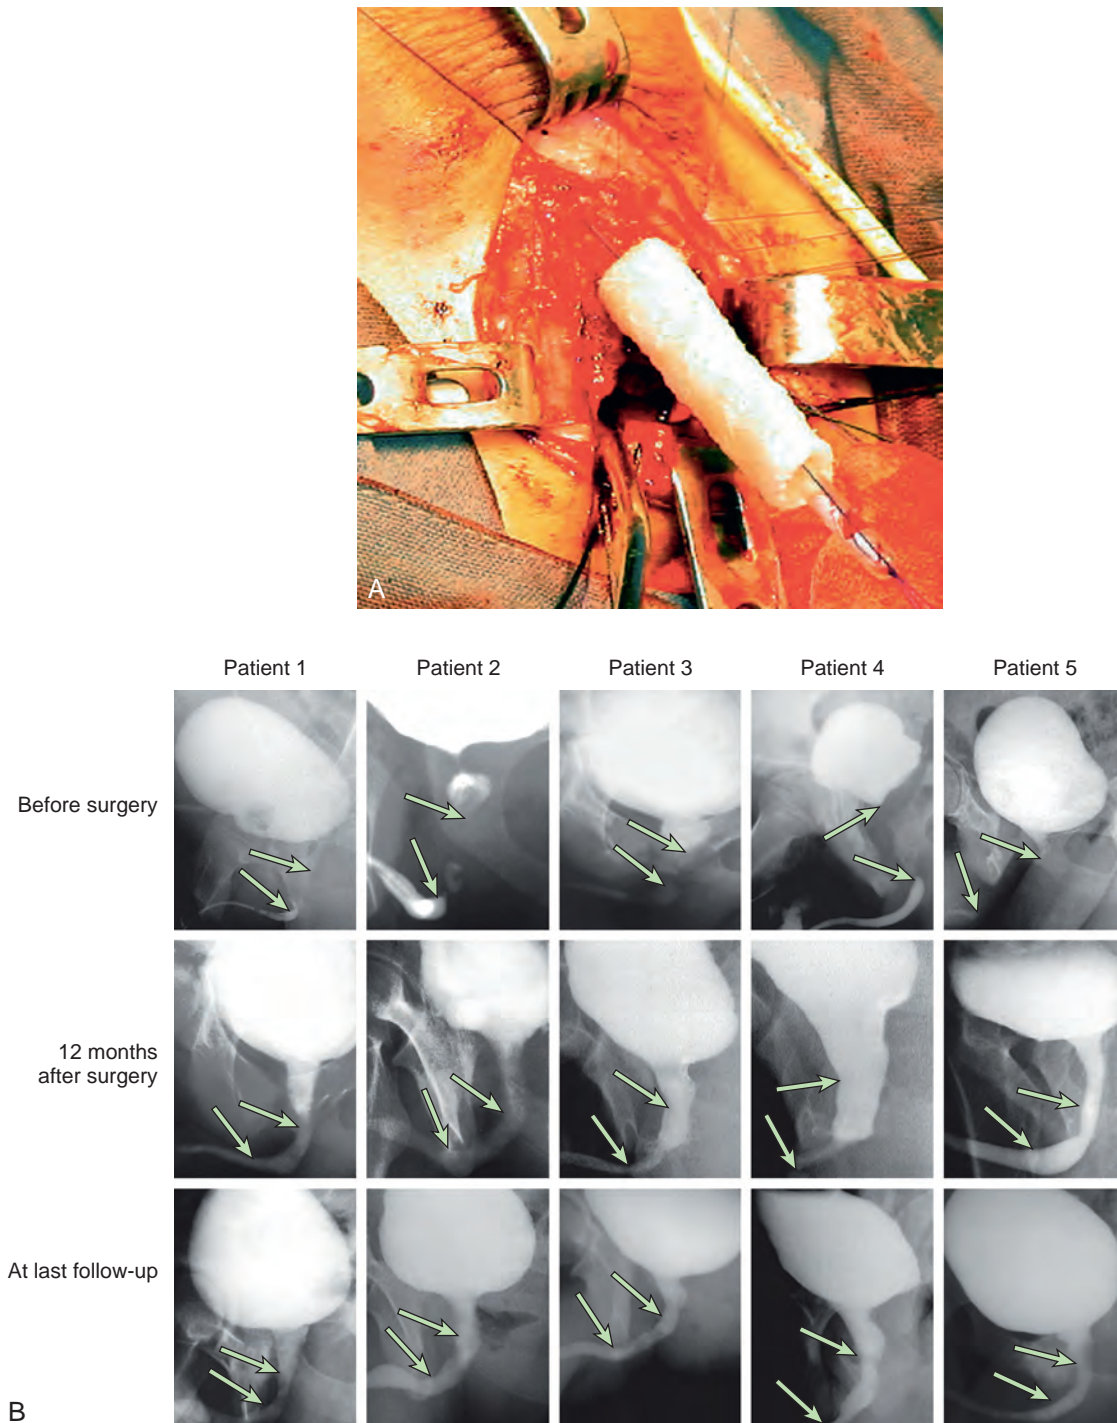

Figure 20-5. Tissue urethra implantation and clinical outcome in five patients after traumatic injury. **A**, An autologous cell-seeded graft sutured to the normal urethral margins from the first patient. **B**, Voiding cystourethrograms of five patients before surgery (arrows show the abnormal margins), 12 months after surgery (arrows show margins of tissue-engineered urethras), and at last follow-up to 7 years after surgery (arrows show margins of tissue-engineered urethras).

fibrosis, and scar formation. Cell-seeded matrices implanted in wound beds are able to further lengthen the distance for normal tissue formation without initiating an adverse fibrotic response. Studies in the field of regenerative medicine have shown that very large defects, greater than 30 cm, can be successfully treated using cell-seeded scaffolds. This explains the described experimental and clinical results noted with urethral repair. Nonseeded matrices are able to replace urethral segments when used in an onlay fashion because of the short distances required for tissue

ingrowth. However, if a tubularized urethral repair is needed, the matrices need to be seeded with autologous cells to avoid the risk of stricture formation and poor tissue development.

Bladder

Currently, gastrointestinal segments are commonly used as tissues for bladder replacement or repair. However, gastrointestinal tissues are designed to absorb specific solutes, whereas bladder tissue is

designed for the excretion of solutes. When gastrointestinal tissue is in contact with the urinary tract, multiple complications may ensue, such as infection, metabolic disturbances, urolithiasis, perforation, increased mucus production, and malignancy (McDougal, 1992). Because of the problems encountered with the use of gastrointestinal segments, numerous investigators have attempted alternative reconstructive procedures for bladder replacement or repair. These include autoaugmentation (Cartwright and Snow, 1989a, 1989b) and ureterocystoplasty (Adams et al, 1998). In addition, alternate methods for bladder reconstruction have been explored, such as the use of tissue expansion (Lailas et al, 1996; Satar et al, 1999) and regenerative medicine with cell transplantation.

Matrices for Bladder Regeneration

Over the last few decades, several bladder wall substitutes have been used in attempts at regeneration, with both synthetic and organic materials. Synthetic materials that have been tried in experimental and clinical settings include polyvinyl sponge, Teflon, collagen matrices, Vicryl (PGA) matrices, and silicone. Most of these attempts failed because of mechanical, structural, functional, or biocompatibility problems. Usually, permanent synthetic materials used for bladder reconstruction succumb to mechanical failure and urinary stone formation, and use of degradable materials leads to fibroblast deposition, scarring, graft contracture, and a reduced reservoir volume over time (Atala, 1995, 1998).

There has been a resurgence in the use of various collagen-based matrices for tissue regeneration. Nonseeded allogeneic acellular bladder matrices have served as scaffolds for the ingrowth of host bladder wall components. The matrices are prepared by mechanically and chemically removing all cellular components from bladder tissue (Probst et al, 1997; Yoo et al, 1998b). The matrices serve as vehicles for partial bladder regeneration, and relevant antigenicity is not evident.

Cell-seeded allogeneic acellular bladder matrices were used for bladder augmentation in dogs (Yoo et al, 1998b). Biomaterials preloaded with cells before their implantation showed better tissue regeneration compared with biomaterials implanted with no cells, in which tissue regeneration depended on ingrowth of cells from the surrounding tissue. The acellular collagen matrices can be enhanced with growth factors to improve bladder regeneration (Kikuno et al, 2009).

SIS, a biodegradable, acellular, xenogeneic collagen-based tissue-matrix graft, was first described in the early 1960s as an acellular matrix for tissue replacement in the vascular field (Rotthoff et al, 1964, 1969). The matrix is derived from pig small intestine in which the mucosa is mechanically removed from the inner surface and the serosa and muscular layer are removed from the outer surface. Animal studies have shown that the nonseeded SIS matrix used for bladder augmentation is able to regenerate in vivo (Kropp et al, 1996). Histologically, the transitional layer was the same as that of the native bladder tissue but, as with other nonseeded collagen matrices used experimentally, the muscle layer was not fully developed. In vitro contractility studies performed on SIS-regenerated dog bladders showed a decrease in maximal contractile response by 50% from that of normal bladder tissues.

Bladder augmentation using laparoscopic techniques was performed on minipigs with porcine bowel acellular tissue matrix, human placental membranes, or porcine SIS. At 12 weeks' postoperatively the grafts had contracted down to 60% of their original sizes, and histologically the grafts showed predominantly only mucosal regeneration (Portis et al, 2000). Hemicycstectomy and bladder replacement with SIS showed muscle at the graft periphery and center but it consisted of small fused bundles with significant fibrosis at 1 year. Compared with primary bladder closure after hemicycstectomy, no advantage in bladder capacity or compliance was documented (Landman et al, 2004).

In multiple studies using various materials as nonseeded grafts for cystoplasty, the urothelial layer was able to regenerate normally, but the muscle layer, although present, was not fully

developed (Kropp et al, 1996; Sutherland et al, 1996; Probst et al, 1997; Yoo et al, 1998b; Jayo et al, 2008b; Zhang, 2008). Studies involving acellular matrices that may provide the necessary environment to promote cell migration, growth, and differentiation are being conducted (Chun et al, 2007). With continued bladder research in this area, these matrices may have a clinical role in bladder replacement in the future.

Regenerative Medicine for Bladder Using Cell Transplantation

Regenerative medicine with selective cell transplantation may provide a means to create functional new bladder segments (Atala, 1997). The success of cell transplantation strategies for bladder reconstruction depends on the ability to use donor tissue efficiently and to provide the right conditions for long-term survival, differentiation, and growth. Various cell sources have been explored for bladder regeneration. Native cells are currently preferable because they can be used without rejection (Cilento et al, 1994). Amniotic fluid- and bone marrow-derived stem cells can also be used in an autologous manner and have the potential to differentiate into bladder muscle (De Coppi et al, 2007b; Shukla et al, 2008) and urothelium (Anumanthan et al, 2008). Embryonic stem cells also have the potential to differentiate into bladder tissue (Oottamasathien et al, 2007).

Formation of Bladder Tissue

Human urothelial and muscle cells can be expanded in vitro, seeded onto polymer scaffolds, and allowed to attach and form sheets of cells. The cell-polymer scaffold can then be implanted in vivo. Histologic analysis indicated that viable cells were able to self-assemble back into their respective tissue types, and would retain their native phenotype (Atala et al, 1993b). These experiments demonstrated, for the first time, that composite layered tissue-engineered structures could be created de novo.

It has been well established for decades that the bladder is able to regenerate generously over free grafts. Urothelium is associated with a high reparative capacity (de Boer et al, 1994). Bladder muscle tissue is less likely to regenerate in a normal fashion. Both urothelial and muscle ingrowth are believed to be initiated from the edges of the normal bladder toward the region of the free graft (Baker et al, 1958; Gorham et al, 1989). Usually, however, contracture or resorption of the graft has been evident. The inflammatory response toward the matrix may contribute to the resorption of the free graft. It was hypothesized that building the three-dimensional structure constructs in vitro, before implantation, would facilitate the eventual terminal differentiation of the cells after implantation in vivo and would minimize the inflammatory response toward the matrix, thus avoiding graft contracture and shrinkage. A dog study demonstrated a major difference between matrices used with autologous cells (tissue-engineered matrices) and those used without cells (Yoo et al, 1998b). Matrices implanted with cells for bladder augmentation retained most of their implanted diameter, as opposed to matrices implanted without cells for bladder augmentation, in which graft contraction and shrinkage occurred. The histomorphology demonstrated a marked paucity of muscle cells and a more aggressive inflammatory reaction in the matrices implanted without cells.

To better address the functional parameters of tissue-engineered bladders, a canine animal model was designed that required a subtotal cystectomy with subsequent replacement with a tissue-engineered organ (Oberpenning et al, 1999). Cystectomy-only and nonseeded controls maintained average capacities of 22% and 46% of preoperative values, respectively. An average bladder capacity of 95% of the original precystectomy volume was achieved in the cell-seeded tissue-engineered bladder replacements. These findings were confirmed radiographically (Fig. 20-6). Histologically, the nonseeded scaffold bladders presented a pattern of normal urothelial cells with a thickened fibrotic submucosa and a thin layer of muscle

Figure 20-6. Radiographic cystograms in beagles 11 months after subtotal cystectomy without reconstruction (A); with reconstruction using a polymer without cells (B); and with reconstruction with a polymer and cell-seeded tissue-engineered organ (C). Organs after trigone-sparing cystectomy retained a small reservoir. Tissue-engineered neobladders showed a normal configuration and a larger capacity than the trigones grafted with polymer only.

Figure 20-7. Hematoxylin and eosin staining shows histologic results 6 months after surgery (original magnification, $\times 250$). A, Normal canine bladder. B, The bladder dome of the bladder reconstructed with cell-free polymer consists of normal urothelium over a thickened layer of collagen and fibrotic tissue; only scarce muscle fibers are apparent. C, The tissue-engineered neo-organ has a histomorphologically normal appearance. A trilayered architecture consisting of urothelium, submucosa, and smooth muscle is evident.

fibers. The retrieved tissue-engineered bladders showed a normal cellular organization, consisting of a trilayer of urothelium, submucosa, and muscle (Fig. 20-7). These studies, performed with PGA-based scaffolds, have been repeated by other investigators, showing similar results in large numbers of animals long term (Jayo et al, 2008a, 2008b). However, not all scaffolds perform well if a large portion of the bladder needs replacement. In a study using SIS for subtotal bladder replacement in dogs, both the unseeded and

cell-seeded experimental groups showed graft shrinkage and poor results (Zhang et al, 2006b). The type of scaffold used is critical for the success of these technologies. The use of bioreactors, wherein mechanical stimulation is started at the time of organ production, has also been proposed as an important parameter for success (Farhat and Yeger, 2008; Bouhout et al, 2011).

A clinical experience involving engineered bladder tissue for cystoplasty reconstruction was conducted starting in 1998. A small

Figure 20-8. Construction of engineered bladder. A, Scaffold material seeded with cells for use in bladder repair. B, The seeded scaffold is anastomosed to native bladder with running 4-0 polyglycolic sutures. C, Implant covered with fibrin glue and omentum.

pilot study of seven patients was reported, using a collagen scaffold seeded with cells either with or without omentum coverage, or a combined PGA-collagen scaffold seeded with cells and omental coverage (Fig. 20-8). The patients who underwent reconstruction with the engineered bladder tissue created with the PGA-collagen cell-seeded scaffolds with omental coverage showed increased compliance, decreased end-filling pressures, increased capacities, and longer dry periods over time (Atala et al, 2006). Although the experience is promising in terms of showing that engineered tissues can be implanted safely, it is just a start in terms of accomplishing the goal of engineering fully functional bladders. This was a limited clinical experience, and the technology is not yet ready for wide dissemination; further experimental and clinical studies are required. FDA phase 2 studies have now been completed.

From the aforementioned studies it is evident, as with the urethral studies, that the use of cell-seeded matrices is superior to the use of nonseeded matrices for the creation of engineered bladder tissues. Although advances have been made with the engineering of bladder tissues, many challenges remain. Current research in many centers is aimed at the development of biologically active and “smart” biomaterials that may improve tissue regeneration. Also, similar engineering techniques are now being used for patients with bladder cancer, who are having engineered urinary conduits implanted after cystectomy (Hyndman et al, 2012). Stem cells derived from fat can be differentiated into smooth muscle for the conduits, thus avoiding native cells from bladder cancer patients (Basu et al, 2012).

Bladder Cell Therapies

Both urinary incontinence and vesicoureteral reflux are common conditions affecting the genitourinary system for which injectable therapy within the bladder may be useful. The ideal substance for the endoscopic treatment of reflux and incontinence should be injectable, nonantigenic, nonmigratory, volume stable, and safe for human use (Kershner et al, 1999). Toward this goal, long-term studies were conducted to determine the effect of injectable chondrocytes in vivo (Atala et al, 1993a). This system was adapted for the treatment of reflux in a porcine model (Atala et al, 1994).

The first human application of cell-based regenerative medicine technology for urologic applications occurred with the injection of chondrocytes for the correction of vesicoureteral reflux in children and for urinary incontinence in adults. Phase 1 trials showed an approximate success rate of 80% at both 3 and 12 months postoperatively (Bent et al, 2001). Patients with vesicoureteral reflux were treated at 10 centers throughout the United States. The patients had a similar success rate as with other injectable substances in terms of cure. The overall success rate in 29 children (47 ureters) was 86%. At 1-year follow-up, reflux correction was maintained in 70% of the

ureters. Chondrocyte formation was not noted in patients who had treatment failure (Diamond et al, 1999).

With cell therapy techniques, the use of autologous smooth muscle cells was explored for both urinary incontinence and vesicoureteral reflux applications (Cilento et al, 1995). In vivo experiments were conducted in minipigs, and reflux was successfully corrected. The potential use of injectable, cultured myoblasts for the treatment of stress urinary incontinence has been investigated in animal models (Chancellor et al, 2000; Yokoyama et al, 2000; Cannon et al, 2003; Lee et al, 2003; Strasser et al, 2004; Kwon et al, 2006; Mitterberger et al, 2007b). Intrinsic muscle precursor cells have also been shown to play an active role in the regeneration of injured striated urethral sphincter (Yiou et al, 2003a, 2003b). A canine model of irreversible urethral sphincter injury was also created to test these technologies (Eberli et al, 2008, 2012).

Other cell types have also been used for urinary incontinence. The use of amniotic fluid-derived stem cells has been tested experimentally (Chun et al, 2012; Kim et al, 2012a). The use of lipoaspirate cells has also been proposed for the treatment of urinary incontinence. The lipoaspirate cells were injected into mice bladders and urethras, and regenerated muscle tissue (Jack et al, 2005; Fu et al, 2010; Zhao et al, 2011). The cells were used in the clinical setting in patients in an autologous manner in a pilot study with adequate results (Yamamoto et al, 2012).

Several clinical trials using myoblast injection have been conducted in patients with stress urinary incontinence (Mitterberger et al, 2007a). The authors compared the effectiveness and tolerability of ultrasonography-guided injections of autologous cells with those of endoscopic injections of collagen for stress incontinence in 63 patients, showing improved results for the patients receiving the myoblasts. However, controversy surrounding the trial ensued and the paper was retracted. In another trial, myoblasts isolated from the abdominal wall vasculature were injected in a series of bladder exstrophy patients with urinary incontinence. The authors reported that 88% of patients were socially dry, described as daytime dryness lasting more than 3 hours. The patients were also on a pelvic floor electrical stimulation and pelvic floor exercise program (Kajbafzadeh et al, 2008). Another study described the use of autologous muscle-derived stem cell injection to treat stress urinary incontinence. After 1 year, one of eight women achieved total continence and five reported improvement (Carr et al, 2008). A 24% success rate was obtained in a patient trial using myoblasts delivered with ultrasound guidance (Blaganje and Lukianović, 2012). Activity has increased in the area of cell therapy for urinary incontinence in the last several years. Further trials and follow-up will be needed to determine long-term efficacy.

Cell therapy studies have also been conducted for radiation cystitis. Bone marrow cells have been injected in rats (Imamura et al, 2012). Both amniotic fluid and bone marrow stem cells have been used to ameliorate bladder dysfunction in a Parkinson animal

model (Soler et al, 2012). Also, recently, mechanisms are being elucidated for the regeneration of bladder stem cells in situ—for example, with a Hedgehog and Wnt feedback system (Shin et al, 2011). These studies are certain to advance with the generation of small molecules and pharmacologic agents for regenerative medicine (Lu and Atala, 2013).

Ureters

Various strategies have been used to engineer ureteral tissues experimentally, but these have not yet been implanted in patients.

Additional information on regenerative medicine efforts in the ureter appears on the Expert Consult website.

Male Genital and Reproductive Tissues

Reconstructive surgery is required for a wide variety of pathologic penile conditions, including penile carcinoma, trauma, severe erectile dysfunction, and congenital conditions such as ambiguous genitalia, hypospadias, and epispadias. One of the major limitations of genital reconstructive surgery is the availability of sufficient autologous tissue. Nongenital autologous tissue sources have been used for decades. Phallic reconstruction was initially attempted in the late 1930s, with rib cartilage used as a stiffener for patients with traumatic penile loss (Frumppkin, 1944; Goodwin and Scott, 1952). This method, involving multiple staged surgeries, was soon discouraged because of the unsatisfactory functional and cosmetic results. Silicone rigid prostheses were popularized in the 1970s and have been used widely (Small et al, 1975; Bretan, 1989). However, biocompatibility issues have been a problem in selected patients (Thomalla et al, 1987; Nukui et al, 1997).

Research has also been performed looking at the possibility of creating prostheses with cells; this information appears on the Expert Consult website.

Reconstruction of Penile Corpora

One of the major components of the phallus is corporeal smooth muscle. The creation of autologous functional and structural corporeal tissue de novo would be beneficial. Initial experiments showed that cultured human corporeal smooth muscle cells may be used in conjunction with biodegradable polymers to create corpus cavernosum tissue de novo (Kershen et al, 2002). When grown on collagen, corporeal cavernosal ECs formed capillary structures that created complex three-dimensional capillary networks. In a subsequent study, human corporeal smooth muscle cells and ECs seeded on biodegradable polymer scaffolds were able to form vascularized cavernosal muscle when implanted in vivo (Park et al, 1999). A naturally derived acellular corporeal tissue matrix that possesses the same architecture as native corpora was developed. Acellular collagen matrices were derived from processed donor rabbit corpora using cell lysis techniques. Human corpus cavernosal muscle and ECs were derived from donor penile tissue, and the cells were expanded in vitro and seeded on the acellular matrices. The matrices were covered with the appropriate cell architecture 4 weeks after implantation (Falke et al, 2003). The use of these tissue-derived matrices as cell-delivery scaffolds allowed for the development of adequate structural and vascular corpora cavernosa constructs.

To look at the functional parameters of the engineered corpora, acellular corporeal collagen matrices were obtained from donor rabbit penis and autologous corpus cavernosal smooth muscle, and ECs were harvested, expanded, and seeded on the matrices. An entire cross-sectional segment of protruding rabbit phallus was excised, leaving the urethra intact, and the cell-seeded matrices were interposed into the excised corporeal space. Functional and structural parameters (cavernosography, cavernosometry, mating behavior, and sperm ejaculation) were followed, and histochemical, immunocytochemical, and Western blot analyses were performed up to 6 months after implantation. The engineered corpora cavernosa achieved adequate structural and functional parameters (Kwon et al, 2002). This technology was further confirmed when the entire

rabbit phallus corpora were removed and replaced with the engineered scaffolds seeded with both corporeal endothelial and smooth muscle cells (Fig. 20-9). The experimental corporeal bodies demonstrated intact structural integrity by cavernosography and showed similar pressure by cavernosometry when compared with normal controls (Fig. 20-10). The control rabbits without cells failed to show normal erectile function throughout the study period. Mating activity in the animals with the engineered corpora appeared normal by 1 month after implantation. The presence of sperm was confirmed during mating, and sperm was present in all the rabbits with the engineered corpora. The female rabbits mated with the animals implanted with engineered corpora and also conceived and delivered healthy pups. Animals implanted with the matrix alone were unable to demonstrate normal mating activity and failed to ejaculate into the vagina. Grossly, the corporeal implants with cells showed continuous integration of the graft into native tissue. Histologically, sinusoidal spaces and walls, lined with endothelium and smooth muscle, were observed in the engineered grafts. Grafts without cells contained fibrotic tissue and calcifications with sparse corporeal elements. Each cell type was identified immunocytochemically and by Western blot analyses. The engineered corporeal tissues were able to contract and relax in response to electric field and pharmacologic stimulation, and the contractile response reached levels similar to normal corpora by 6 months after implantation (Chen et al, 2010).

The aforementioned series of studies demonstrates that penile corpora cavernosa tissue can be engineered. The engineered tissue is able to achieve adequate structural and functional parameters sufficient for erection, copulation, ejaculation, conception, and delivery experimentally. Further studies will be needed to confirm the long-term functionality of these organs. In addition, further studies are needed to show that human structures can also be engineered.

Penile Cell Therapy

Various cell therapies have been proposed and used experimentally for erectile dysfunction. ECs have been used in animal models to reverse erectile dysfunction (Gou et al, 2011). Mesenchymal stem cells have been used either alone or in combination with matrices (Lin et al, 2011; Kim et al, 2012b), showing an improvement in function in mice. The delivery of human bone marrow–derived stem cells to the periprosthetic region in rats led to improved response after the cells were injected in the corpora (Qiu et al, 2011; You et al, 2013). Muscle-derived stem cells showed the prevention of erectile dysfunction after cavernosal injury in rats (Kovanecz et al, 2012). Adipose-derived cells have also been used in rodents, showing reversal of corporeal damage, with or without growth factors (Orabi et al, 2012; Qiu et al, 2012; Ryu et al, 2012; Liu et al, 2013). Similar cells have also been used to treat Peyronie disease (Castiglione et al, 2013). Various cell populations are making a transition into the clinic. Long-term studies will be needed to gauge the full impact of these therapies.

Testis

Leydig cells are the major source of testosterone production in males. Patients with testicular dysfunction require androgen replacement for somatic development. Conventional treatment for testicular dysfunction consists of periodic intramuscular injections of chemically modified testosterone or, more recently, skin patch applications. However, long-term nonpulsatile testosterone therapy is not optimal and can cause multiple problems, including erythropoiesis and bone density changes.

A system was designed wherein Leydig cells were microencapsulated for controlled testosterone replacement. Microencapsulated Leydig cells offer several advantages, such as serving as a semipermeable barrier between the transplanted cells and the host's immune system, as well as allowing for the long-term physiologic release of testosterone. Purified Leydig cells were isolated and encapsulated in an alginate-poly-L-lysine solution. The encapsulated Leydig cells

Collagen tubular sponges have been used to transplant bladder cells for replacement of ureteral segments in dogs. The study showed severe stricture formation and papillary mucosal thickening at the anastomotic sites. In addition, muscle regeneration into the collagen grafts was not evident (Tachibana et al, 1985).

Ureteral decellularized matrices have been used as a scaffold both for the ingrowth of ureteral tissue (Dahms et al, 1997) and as a cell delivery vehicle using urothelial and bone marrow-derived cells (Matsunuma et al, 2006). Laparoscopic segmental ureteral replacement with an acellular matrix prepared from ureters and small-intestinal submucosa was performed in minipigs (Shalhav et al, 1999). At 12 weeks, all animals had complete obstruction at the level of the replacement. Ureteral replacement with polytetrafluoroethylene (Teflon) grafts was attempted in dogs, also with poor functional results (Baltaci et al, 1998). Nonseeded ureteral collagen acellular matrices were tubularized and used to replace 3-cm segments of canine ureters. At the time of sacrifice there was moderate to marked hydronephrosis above the level of the new tube in all dogs, with significant narrowing of the ureteral lumen up to complete occlusion (Osman et al, 2004).

Cell-seeded biodegradable polymer scaffolds have been used as cell transplantation vehicles to reconstruct ureteral tissues. In one study, urothelial and smooth muscle cells isolated from bladders and expanded in vitro were seeded onto PGA scaffolds with tubular configurations and implanted subcutaneously into athymic mice. After implantation, the urothelial cells proliferated to form a multilayered luminal lining of tubular structures, whereas the smooth muscle cells organized into multilayered structures surrounding the urothelial cells. Abundant angiogenesis was evident. The degradation of the polymer scaffolds resulted in the eventual formation of natural urothelial tissues (Atala et al, 1993b). This study suggested that it was possible to engineer urologic tissues containing multiple cell types. This approach was expanded to replacement of ureters in dogs by transplantation of smooth muscle cells and urothelial cells on tubular polymer scaffolds (Yoo et al, 1995). Amniotic membranes have also been used experimentally as a ureteral replacement (Ismail et al, 2009). The limitations of transferring this technology to humans are the small number of patients requiring this type of tissue, and the large investment that would be required for regulatory approval.

Engineered Penile Prostheses

Although silicone is an accepted biomaterial for penile prostheses, biocompatibility is a concern (Thomalla et al, 1987; Nukui et al, 1997). The use of a natural prosthesis composed of autologous cells may be advantageous. A feasibility study for the creation of natural penile prostheses made of cartilage was performed initially (Yoo et al, 1998a).

Cartilage harvested from the articular surface of calf shoulders was isolated, grown, and expanded in culture. The cells were seeded onto preformed cylindric PGA polymer rods and implanted in mice. At retrieval, all polymer scaffolds seeded with cells formed milky-white, rod-shaped, solid cartilage structures, maintaining their pre-implantation size and shape. In a subsequent study using an autologous system, the feasibility of applying the engineered

cartilage rods in situ was investigated (Yoo et al, 1999). Autologous chondrocytes harvested from rabbit ear were grown and expanded in culture. The cells were seeded onto biodegradable PLLA-coated PGA polymer rods and implanted into the corporeal spaces of rabbits. Examination at retrieval showed the presence of well-formed, milky-white cartilage structures within the corpora at 1 month. The animals were able to copulate and impregnate their female partners. In another study, human cartilage rods were engineered in vitro for potential use as penile prostheses. Chondrocytes isolated from human ear were seeded on rod-shaped biodegradable polymer scaffolds (1.2 cm in diameter, 6.0 cm long). The engineered human cartilaginous rods were flexible, elastic, and able to withstand high degrees of compressive forces. The mechanical properties were comparable to those of commercially available silicone prostheses (Kim et al, 2002).

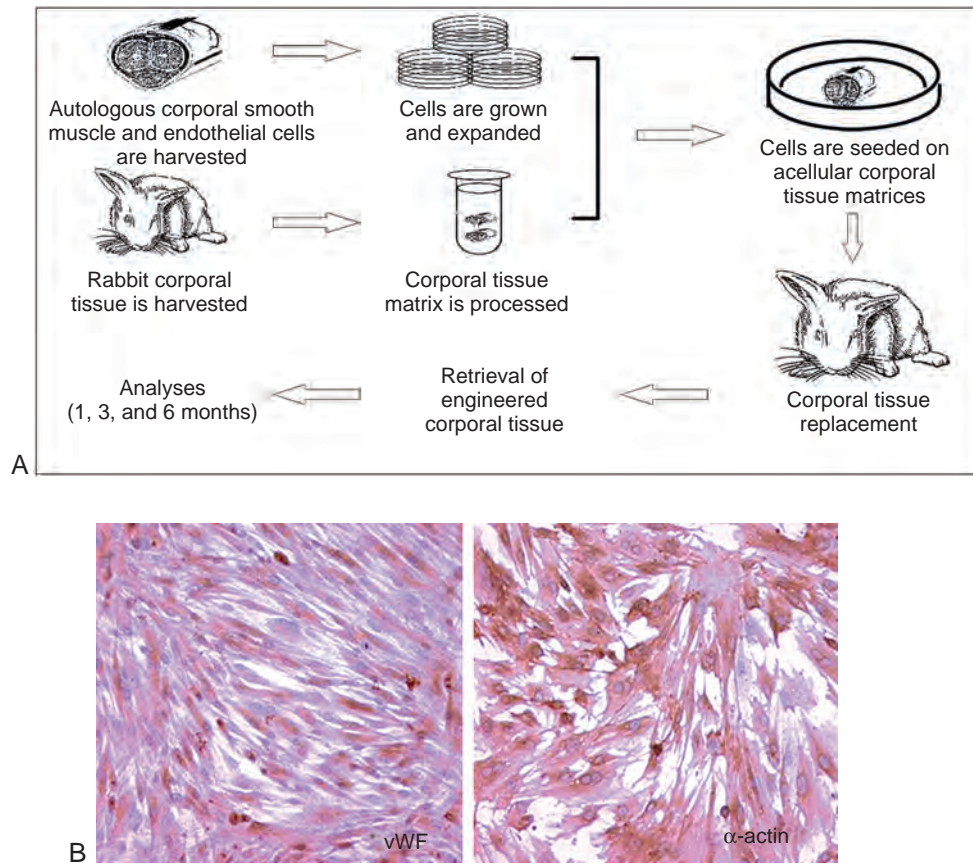

Figure 20-9. Isolation and culture of autologous corporeal cavernosal cells for tissue engineering. **A,** Overall study design. **B,** Culture expanded endothelial cells (*left*) show positive expression of cell-specific marker von Willebrand factor (vWF) protein, and smooth muscle cells show expression of smooth muscle-specific α -actin (*right*).

were injected into castrated animals, and serum testosterone was measured serially; the animals were able to maintain testosterone levels in the long term (Machluf and Atala, 1998). These studies suggest that microencapsulated Leydig cells may be able to replace or supplement testosterone in situations where anorchia or testicular failure is present. A novel technique to isolate Leydig stem cells and to study Leydig cell development has also been described (Lo et al, 2004). The successful transplantation of functional Leydig stem cells into a hypogonadal recipient showed that the *de novo* synthesis of testosterone is possible.

Further studies showed that testicular prostheses created with chondrocytes in bioreactors could be loaded with testosterone. The prostheses were implanted in athymic mice with bilateral anorchia, and testosterone was released long term, maintaining the androgen level at a physiologic range (Raya-Rivera et al, 2008). One could envision combining the Leydig cell technology previously described with engineered prostheses for the long-term functional replacement of androgen levels.

The ability to have spermatogenesis for infertility purposes has been a major area of interest in the last several decades. The introduction of spermatogonial stem cell transplantation in mice opened new avenues to the field of male infertility treatment (Brinster and Zimmermann, 1994). Since the discovery of the feasibility of spermatogonial stem cell isolation and autotransplantation, it has been demonstrated in several species including nonhuman primates. The first successful isolation of human spermatogonial stem cells in 2002 showed that the cells were able to colonize and survive for 6 months in mice recipient testes (Nagano et al, 2002). The same group had been able to show the restoration of fertility in mice with the transplantation of male germline stem cells (Ogawa et al, 2000). Sertoli cells, the main component of the testicular germ cell niche,

were also able to restore fertility in mice (Kanatsu-Shinohara et al, 2005). More recently, successful autologous and allogeneic spermatogonial stem cell transplantation was demonstrated in adult and prepubertal macaque testes that were previously rendered infertile with alkylating chemotherapy (Hermann et al, 2012). **In vitro** propagation of human spermatogonial stem cells from both adult and pubertal testes has been established (Sadri-Ardekani et al, 2009). In these systems, human spermatogonial stem cells are supported by a feeder layer from the same patient's testicular somatic cells. Human spermatogonial stem cells could be maintained *in vitro* for more than 15 weeks (Sadri-Ardekani et al, 2011). Optimization of this culture system based on FDA regulations and current good tissue practice (CGTP) requirements is imperative before use in a clinical application.

Female Genital and Reproductive Tissues

Congenital malformations of the uterus may have profound implications clinically. Patients with cloacal exstrophy and intersex disorders may not have sufficient uterine tissue present for future reproduction. The possibility of engineering functional uterine tissue using autologous cells was investigated (Wang et al, 2003). Autologous rabbit uterine smooth muscle and epithelial cells were harvested, grown, and expanded in culture. These cells were seeded onto preconfigured uterine-shaped biodegradable polymer scaffolds, which were then used for subtotal uterine tissue replacement in the corresponding autologous animals. On retrieval 6 months after implantation, histologic, immunocytochemical, and Western blot analyses confirmed the presence of uterine tissue components. Biomechanical analyses and organ bath studies showed that the functional characteristics of these tissues were similar to those of

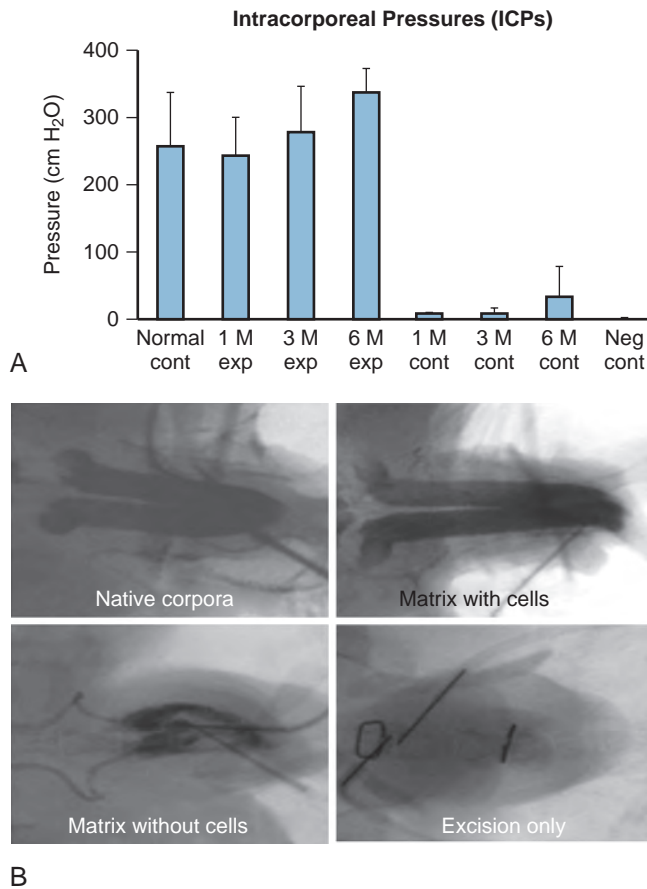

Figure 20-10. Cavernosometry and cavernosography. A, Cavernosometry shows that all rabbits implanted with the bioengineered corpora after complete penile corporeal excision had sufficient intracorporeal pressure (ICP) to attain erection ($n = 12$). The levels of ICP were comparable to native corpora ($n = 12$). B, Cavernosography shows a homogeneous appearance of corpora in the bioengineered group ($n = 12$) similar to the native corpora ($n = 16$), numerous filling defects in the unseeded control group ($n = 12$), and major filling gaps in the negative control group ($n = 3$).

normal uterine tissue. Breeding studies using these engineered uteri are currently being performed.

Similarly, several pathologic conditions, including congenital malformations and malignancy, can adversely affect normal vaginal development or anatomy. Vaginal reconstruction has traditionally been challenging because of the paucity of available native tissue.

Many techniques and materials can be used successfully for vaginal reconstruction. The most common surgical reconstructive approach involves creating a canal by dissecting the potential neovaginal space and subsequently lining the pelvic canal with a graft. Multiple materials have been used to line the surgically created cavity, including mostly full- or split-thickness skin grafts, but also cellulose (Dornelas et al, 2012), decellularized matrices derived from skin or intestinal mucosa (Ding et al, 2013; Zhu et al, 2013), and vaginal epithelia (Panici et al, 2007).

The feasibility of engineering vaginal tissue with cells in vivo was also investigated (De Filippo et al, 2003). Vaginal epithelial and smooth muscle cells of female rabbits were harvested, expanded, and seeded onto biodegradable polymer scaffolds, and the cell-seeded constructs were then implanted into both athymic mice ex situ and rabbits as a full replacement of the organ. Functional studies in the tissue-engineered constructs showed similar properties to those of normal vaginal tissue. When these constructs were used for autologous total vaginal replacement in a rabbit model, patent functional vaginal structures were noted

in the tissue-engineered specimens, whereas the non-cell-seeded structures were noted to be stenotic (De Filippo et al, 2008) (Fig. 20-11). These studies indicated that a regenerative medicine approach to clinical vaginal reconstruction would be a realistic possibility. Clinical trials are currently being conducted.

Ovarian tissue is essential for fertility. Recent studies have shown that ovarian cells can be derived from stem cell populations. The cells can lead to the production of oocytes and embryos (Choi et al, 2011). Implanted oocytes have shown full functionality, including fertility and live delivery in mice.

Cell therapies have also been used to enhance the functionality of the ovary experimentally in animal models. Adipose-, amniotic fluid-, umbilical cord-, and bone marrow-derived stem cells have all resulted in a return of experimentally damaged ovarian function in animal models (Fu et al, 2008; Abd-Allah et al, 2013; Lai et al, 2013; Sun et al, 2013; Wang et al, 2013).

Renal Structures

Although the kidney was the first organ to undergo substitution with an artificial device and the first successfully transplanted organ (Guild et al, 1955), current modalities of treatment are far from satisfactory. Dialysis remains the most common treatment for renal failure. Renal tissue is arguably one of the most difficult tissues to replicate in the laboratory. The kidney is a complex organ, and the unique structural and cellular heterogeneity present within this organ creates many challenges. The system of nephrons and collecting ducts within the kidney is composed of multiple functionally and morphologically distinct segments. For this reason, appropriate conditions must be provided to ensure the long-term survival, differentiation, and growth of many types of cells. Efforts in the area of kidney tissue regeneration have focused on the development of reliable cell sources (Prockop, 1997; Kale et al, 2003; Lin et al, 2003; Ikarashi et al, 2005; Lin et al, 2005; Yokoo et al, 2005). Moreover, optimal growth conditions have been extensively investigated to provide adequate enrichment to achieve stable renal cell expansion systems (Milici et al, 1985; Carley et al, 1988; Humes et al, 1992; Schena, 1998).

Isolation of particular cell types that produce specific factors may be a good approach for selective cell therapies. For example, renal cells that produce erythropoietin have been isolated in culture, and these cells could eventually be used to treat anemia that results from end-stage renal failure (AbouShwareb et al, 2008; Gyabaah et al, 2012). These cells have also been used to improve renal function in a model of chronic kidney disease (Yamaleyeva et al, 2012). Defined primary cells from the kidney have been studied extensively and used to reconstitute human function (Guimaraes-Souza et al, 2012). More ambitious approaches involve working toward the goal of total renal function replacement. To create kidney tissue that would deliver full renal function, a culture containing all of the cell types comprising the functional nephron units should be used. Optimal culture conditions to nurture renal cells have been extensively studied, and cells grown under these conditions have been reported to maintain their cellular characteristics (Lanza et al, 2002). Cells obtained through the initial process of nuclear transfer have been retrieved and expanded from cloned tissue. Moreover, renal cells placed in a three-dimensional culture environment are able to reconstitute into renal structures. In vitro generated kidney constructs were implanted in the renal capsule region in rats, and they vascularized and formed glomeruli (Joraku et al, 2009).

Recent investigative efforts in the search for a reliable cell source have been expanded to stem and progenitor cells. Use of these cells for tissue regeneration is attractive because of their ability to differentiate and mature into specific cell types needed. This is particularly useful when primary renal cells are unavailable as a result of extensive tissue damage. Bone marrow-derived human mesenchymal stem cells have been shown to be a potential source because of their ability to differentiate into several cell lineages (Ikarashi et al, 2005). The creation of adequate experimental models of renal failure has been critical for the testing of various cell therapies (Wang et al, 2013). Bone marrow-derived cells have been shown to

Figure 20-11. Appearance of tissue-engineered neovaginas. A, Tubular polymer scaffold after cell seeding and 1 week in vitro culture, before implantation in vivo. participate in kidney development when they are placed in a rat embryonic niche that allows for continued exposure to a repertoire of nephrogenic signals (Yokoo et al, 2005). The major cell source of kidney regeneration was found to originate from intrarenal cells in an ischemic renal injury model (Lin et al, 2005). Systemic administration of bone marrow–derived mesenchymal stem cells in mice has led to prevention of kidney damage in various animal models (Humphreys and Bonventre, 2008; Lin, 2008; Morigi et al, 2010). Autologous bone marrow cells have been used clinically for the treatment of allograft rejection after transplantation in a pilot study (Reinders et al, 2013). Other trials are also currently underway with bone marrow–derived stem cells and with primary renal cells, and it is still early to define the outcomes.

Other stem cell types, such as hESCs (Lin, 2006; Bruce et al, 2007), induced pluripotent stem cells (Osafune, 2010; Song et al, 2012), and human amniotic fluid and placental stem cells (Perin et al, 2007; Hauser et al, 2010) can also lead to renal differentiation and reversal of renal injury in animal models. Developmental approaches to kidney regeneration have also been studied, but these are mostly research-driven approaches without a direct clinical pathway.

Regenerative Medicine Approaches to Kidney Regeneration

The ability to grow and expand renal cells is one of the essential requirements in engineering tissues. The feasibility of achieving renal cell growth, expansion, and in vivo reconstitution using regenerative medicine techniques has been investigated (Atala et al, 1991). Donor rabbit kidney cells including distal tubules, glomeruli, and proximal tubules were plated separately in vitro and after expansion were seeded onto biodegradable PGA scaffolds.

Histologic examination demonstrated progressive formation and organization of the nephron segments within the polymer fibers with time. These results demonstrated that renal-specific cells can be successfully harvested and cultured and can subsequently attach to artificial biodegradable polymers. However, it was unclear whether the tubular structures reconstituted de novo from dispersed renal elements or if they merely represented fragments of donor tubules that survived the original dissociation and culture processes intact. Further investigation was conducted to examine the process (Fung et al, 1996). Mouse renal cells were harvested and expanded in culture. Subsequently, single isolated cells were seeded on biodegradable polymers and implanted into immune-competent syngeneic hosts. Renal epithelial cells were observed to reconstitute into tubular structures in vivo. Sequential analyses of the retrieved implants over time demonstrated that renal epithelial cells first organized into a cordlike structure with a solid center. Subsequent canalization into a hollow tube could be seen by 2 weeks. Histologic examination with nephron segment-specific lactins showed successful reconstitution of proximal tubules, distal tubules, loop of Henle, collecting tubules, and collecting ducts. These results showed that single suspended cells are capable of reconstituting into tubular structures, with homogeneous cell types within each tubule.

In a subsequent study mouse renal cells were harvested, expanded in culture, and seeded onto a tubular device constructed from polycarbonate (Yoo et al, 1996). The tubular device was connected at one end to a Silastic catheter that terminated into a reservoir. The device was implanted subcutaneously in athymic mice. Histologic examination of the implanted device demonstrated extensive vascularization as well as formation of glomeruli and highly organized tubulelike structures that were consistent with proximal and distal tubular cells and the cells of the thin ascending loop of Henle. The fluid collected from the reservoir suggested that the tubules are

Developmental Approaches to Kidney Regeneration

Transplantation of a kidney precursor, such as the metanephros, into a diseased kidney has been proposed as a possible method for functional restoration. In an animal study, human embryonic metanephroi transplanted into the kidneys of an immunodeficient mouse model have developed into mature kidneys (Dekel et al, 2003). The transplanted metanephroi produced urinelike fluid; however, they failed to develop ureters. This study suggests that development of an *in vitro* system in which metanephroi could be grown may lead to transplant techniques that could produce a small replacement kidney within the host. In another study, the metanephros was divided into mesenchymal tissue and ureteral buds, and each of the tissue segments was cultured *in vitro* (Steer et al, 2002). After 8 days in culture, each portion of the mesenchymal tissues had grown to the original size. A similar method was used for ureteral buds, which also propagated. These studies were expanded further by staging renal structure reconstitution *in vitro* and later implanting these structures *in vivo* in a mouse model (Rosines et al, 2007). These studies indicated that if the mesenchyme and ureteral buds were placed together and cultured

in vitro, a metanephros-like structure would develop, which suggests that the metanephros could be propagated under optimal conditions.

In another study, transplantation of metanephroi into a nonimmunosuppressed rat omentum showed that the implanted metanephroi were able to undergo differentiation and growth that was not confined by a tight organ capsule (Rogers et al, 1998). When the metanephroi with an intact ureteric bud were implanted, the metanephroi were able to enlarge and become kidney-shaped tissue within 3 weeks. The metanephroi transplanted into the omentum were able to develop into kidney tissue structure with a well-defined cortex and medulla. Mature nephrons and collecting system structures were shown to be indistinguishable from those of normal kidneys by light or electron microscopy (Hammerman, 2002a, 2002b). Moreover, these structures became vascularized via arteries that originate at the superior mesenteric artery of the host (Hammerman, 2002a, 2002b). It has been demonstrated that the metanephroi transplanted into the omentum survive for up to 32 weeks postimplantation (Rogers et al, 1999). These studies show that a developmental approach may be a viable option for regenerating renal tissue for functional restoration.

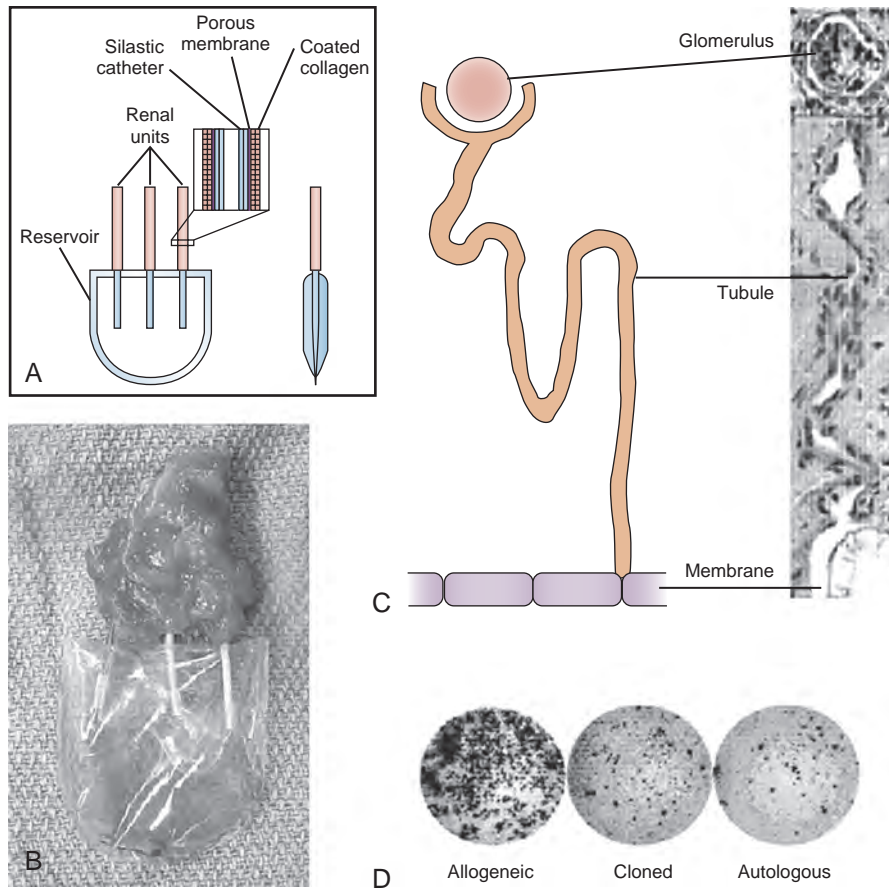

Figure 20-12. Production of kidney tissue by therapeutic cloning and regenerative medicine. **A,** Illustration of the tissue-engineered renal unit. **B,** Renal unit seeded with cloned cells, 3 months after implantation, showing the accumulation of urinelike fluid. **C,** There was a clear unidirectional continuity between the mature glomeruli, their tubules, and the polycarbonate membrane. **D,** ELISpot analyses of the frequencies of T cells that secrete interferon- γ after primary and secondary stimulation with allogeneic renal cells, cloned renal cells, or nuclear donor fibroblasts.

capable of unidirectional secretion and concentration of uric acid. The creatinine assay performed on the collected fluid showed an 8.2-fold increase in concentration as compared with serum. These results demonstrated that single cells from multicellular structures can become organized into functional renal units that are able to excrete high levels of solutes through a urinelike fluid (Yoo et al, 1996).

To determine whether renal tissue could be formed using an alternative cell source, nuclear transplantation (therapeutic cloning) was performed to generate histocompatible tissues, and the feasibility of engineering syngeneic renal tissues in vivo using these cloned cells was investigated (Lanza et al, 2002). Nuclear material from bovine dermal fibroblasts was transferred into unfertilized enucleated donor bovine eggs. Renal cells from the cloned embryos were harvested, expanded in vitro, and seeded onto three-dimensional renal devices. The devices were implanted into the back of the same steer from which the cells were cloned, and were retrieved 12 weeks later. This process produced functioning renal units (Fig. 20-12). Urine production and viability were demonstrated after transplantation back into the nuclear donor animal. Chemical analysis suggested unidirectional secretion and concentration of urea nitrogen and creatinine. Microscopic analysis revealed formation of organized glomeruli and tubular structures. Immunohistochemical and reverse-transcriptase polymerase chain reaction (RT-PCR) analysis confirmed the expression of renal messenger (m)RNA and proteins. These studies demonstrated that cells derived from nuclear transfer can be successfully harvested, expanded in culture, and transplanted

in vivo with the use of biodegradable scaffolds on which the single suspended cells can organize into tissue structures that are genetically identical to those of the host. These studies were the first demonstration of the use of therapeutic cloning for regeneration of tissues in vivo.

A naturally derived tissue matrix with existing three-dimensional kidney architecture would be preferable to the artificial matrix used in the aforementioned experiments because it would allow for transplantation of a larger number of cells, resulting in greater renal tissue volumes. Thus, an acellular collagen-based kidney matrix, which is similar to the native renal architecture, was developed. A subsequent study investigated whether these collagen-based matrices could accommodate large volumes of renal cells and form kidney structures in vivo (Amiel et al, 2000). Renal cells seeded on the matrix adhered to the inner surface and proliferated to confluency by 7 days after seeding. Renal tubular and glomerulus-like structures were observed 8 weeks after implantation. More recent data has confirmed that the creation of larger kidney structures using decellularized kidney matrices and repopulated with cells is possible (Orlando et al, 2012; Sullivan et al, 2012; Arenas-Herrera et al, 2013).

Summary

Regenerative medicine efforts continue to expand in the field of urology and are currently being undertaken for every type of tissue and organ within the urinary system. Most of the efforts expended

in the genitourinary field have occurred within the last several decades. Regenerative medicine strategies involve the use of biomaterials alone, as has been accomplished clinically in patients with urethral disease; biomaterials with cells, as is currently being tested clinically with bladder, urethral, and vaginal tissues; and cell therapies alone, as those applied clinically for erectile dysfunction, Peyronie disease, bladder dysfunction, urinary incontinence, and renal disease. The number of patients and the indications now amenable to regenerative medicine therapies keep increasing. Regenerative medicine is a multidisciplinary field that requires expertise in a wide variety of scientific disciplines, including cell and molecular biology, physiology, pharmacology, chemical engineering, biomaterials, nanotechnology, and clinical sciences. Although modest clinical success has been achieved to date in specific areas, technologies need to be further defined in terms of best patients to treat, because the field continues to be in its infancy. Long-term studies are still essential to ensure safety and efficacy before these technologies have widespread clinical application.

KEY POINTS

- New advances in the ability to expand cells in vitro and to use smart biomaterials and new techniques for vascularization are allowing more complex organs to be engineered.
- Tissue injury can be repaired with minimal fibrosis by the natural wound-healing response for small defects, by the use of nonseeded matrices for defects up to 1 cm from any edge, and by the use of cell-seeded matrices for defects larger than 1 cm.
- Stem cells may provide large repositories of different cell types for tissue and organ repair. Embryonic and induced pluripotent stem cells differentiate easily but may form tumors and may necessitate immunosuppression. Fetal stem cells replicate readily and do not form tumors but may be more limited than embryonic stem cells in their differentiation potential. Adult stem cells may not form tumors or necessitate immunosuppression, but they may not replicate readily.
- Both tissue engineering approaches and injectable cell therapy approaches are being used clinically. The types of cells used, the regenerative medicine strategies applied, the number of patients treated, and the indications for treatment continue to expand.

Vas Deferens

Seminal Vesicles and Ejaculatory Ducts

Prostate

Urethra

Penis

Scrotum

A fundamental comprehension of male genital anatomy is necessary for understanding normal reproduction as well as pathology and treatment options. This chapter provides a general anatomic framework of the surgical, radiographic, and endoscopic anatomy of the normal male reproductive system. As this chapter is dedicated solely to the anatomy of the male reproductive system, please refer to Chapter 68 for further description of pelvic anatomy including bones, soft tissue, circulation, and innervation of the pelvis not directly related to reproduction.

TESTIS

Gross Structure

The testicles are paired organs within the scrotum that include both reproductive and endocrine functions. It is common for the right testis to be lower hanging compared to the left in approximately 85% of men. **The dimensions of the normal testis include a length of 4 to 5 cm, a width of 3 cm, and a depth of 2.5 cm; and the testis normally has a volume of 15 to 25 mL.** The organ is ovoid in shape and white in color (Prader, 1966; Tishler, 1971). There is a small pedunculated or sessile body at the upper pole of the testis, which is known as the appendix testis. A tough capsule envelops the testis, composed from external to internal of the visceral tunica vaginalis, the tunica albuginea, and the tunica vasculosa, before reaching the parenchyma of the testis. The tunica albuginea is composed of smooth muscle cells that pass through collagenous tissue (Langford and Heller, 1973). It is believed that these smooth muscle cells provide the testicular capsule with some ability to contract and may impact arterial flow into the testis. They may also promote the flow of seminiferous tubule fluid on its way out of the testis (Schweitzer, 1929; Rikmaru and Shirai, 1972; Davis and Horowitz, 1978). The attachment to the epididymis is on the posterolateral aspect of the testis (Figs. 21-1 and 21-2).

Microanatomic Architecture

The tunica albuginea invaginates into the testis to form the mediastinum testis, where vessels and ducts traverse the testicular capsule. The mediastinum testis sends septa that attach to the inner surface of the tunica albuginea to form 200 to 300 cone-shaped lobules,

each of which contains one or more convoluted seminiferous tubules. Each lobule contains a centrifugal artery. Seminiferous tubules are coiled and long, with both ends typically ending in the rete testis. The seminiferous tubules contain germ cells and supporting cells including Sertoli cells, fibrocytes, and myoid cells of the basement membrane. Each seminiferous tubule is U-shaped, but if a seminiferous tubule were stretched out from its convoluted form, each would measure nearly 1 m in length. **Each seminiferous tubule in the normal testis contains developing germ cells. The testosterone-producing Leydig cells are interdispersed in the loose tissue around the seminiferous tubules.** The interstitial tissue includes Leydig cells, mast cells, macrophages, nerves, blood vessels, and lymphatic vessels. This interstitial tissue makes up a total of 20% to 30% of the testicular volume (Setchell and Brooks, 1988). Sertoli cells line the seminiferous tubules and rest on the tubular basement membrane. The cellular characteristics of Sertoli cells include a low mitotic index, prominent nucleoli, and nuclei with irregular shapes. There are strong tight junctions between the Sertoli cells, which compartmentalize the seminiferous tubular space into adluminal and basal spaces. The seminiferous tubules straighten out and become tubuli recti toward the apex of each lobule, where they enter the mediastinum testis and anastomose with a network of tubules lined by flattened epithelia. This tubular network is the rete testis and forms 12 to 20 efferent ductules that anastomose into the caput of the epididymis. At this point, the efferent ductules convolute, enlarge, and form conical lobules. Each lobule produces a duct that drains into a single epididymal duct. The epididymal duct would be approximately 6 m in length if it were stretched out. It winds within the epididymis to form the body and the tail of the epididymis, all of which are surrounded by a fibrous sheath. The thickening and straightening of the duct forms the vas deferens as it reaches the tail of the epididymis (Figs. 21-3 and 21-4).

Arterial Supply

There are three arterial supplies to the testis: the testicular (internal spermatic) artery, the artery of the vas deferens (deferential artery), and the cremasteric (external spermatic) artery (Harrison and Barclay, 1948). The testicular artery is the main blood supply to the testis and its diameter is greater than the deferential and

Figure 21-1. The appearance of the testis with its shiny tunica albuginea layer.

Figure 21-2. The appearance of the testicular parenchyma when bivalved. The white nodule at the right inferior margin represents a sarcoid nodule.

cremasteric arteries combined (Raman and Goldstein, 2004). The testicular artery arises from the abdominal aorta and descends in the intermediate stratum of the retroperitoneum to enter the internal inguinal ring. From its aortic origin, it crosses the psoas muscle and the ureter to reach the inguinal ring to enter the spermatic cord. As the testicular artery descends toward the testis, it branches into an internal artery and an inferior testicular artery and into a capital artery to the caput epididymis. There may be variation at the level of this branching, which has been found to occur within the inguinal canal in 31% to 88% of cases (Beck et al, 1992; Jarow et al, 1992). In 56% of cases, a single artery enters the testis. In 31% of cases, there are two branches, and in 13% there are three or more branches of this artery (Korman and Suoranta, 1971). Arterial anastomosis occurs at the head of the epididymis, allowing for a rich blood supply between the testicular and capital arteries. At the tail of the epididymis, arterial anastomoses are formed between the testicular, epididymal, cremasteric, and vasal arteries. The testicular arteries pass into the mediastinum testis and supply the tunica vasculosa in the anterior portion of the upper pole of the testis and the anterior, medial, and lateral portions of the lower pole of the

Figure 21-3. Appearance of the seminiferous tubules under magnification.

testis. Therefore, care must be taken not to devascularize the testis by passing a traction suture through the lower pole, as well as by performing testis biopsies in the medial or lateral surfaces of the upper pole to minimize the risk of vascular injury. The middle of the testis has fewer vessels than the upper or lower poles. The deferential artery derives from the internal iliac artery or from the superior vesical artery. The cremasteric artery derives from the inferior epigastric artery and primarily supplies the tunica vaginalis, but it has branches going to the testis. Centrifugal arteries, which are the individual arteries supplying the seminiferous tubules, pass within the septa containing the seminiferous tubules and branch into arterioles that ultimately become intertubular and peritubular capillaries (Muller, 1957). Although in the case of testicular artery

Figure 21-7. Venous drainage of the testis and epididymis. Note connections between the pampiniform plexus and the saphenous, internal iliac, and external iliac veins.

ligation, the deferential and cremasteric arteries can potentially provide adequate blood supply to the testis, atrophy and/or azoospermia has resulted from testicular artery ligation in adults and children. Men who have undergone vasectomy deserve special attention in preserving the testicular artery in future surgeries such as varicocele because of the risk of having had the deferential artery compromised at the time of vasectomy (Lee et al, 2007) (Figs. 21-5 and 21-6).

Venous Drainage

Unlike most other venous patterns in the human body, veins within the testis do not travel with their corresponding arteries. Small parenchymal veins either drain into a group of veins near the mediastinum testis, or they drain into veins on the surface of the testis (Setchell and Brooks, 1988). These two groups of veins anastomose with each other and the deferential veins to form the pampiniform plexus. The pampiniform plexus is a network of testicular veins that anastomose as they ascend surrounding the testicular artery. This

allows for a countercurrent heat exchange that cools the blood flow within the testicular artery. Ultimately, these veins join one another to form two or three veins at the level of the inguinal canal, and then they form one vein that ascends to drain into the inferior vena cava on the right and into the renal vein on the left side. There may be variations where the testicular veins can anastomose with the external pudendal, cremasteric, and vasal veins; this can allow varicocele ablations to result in recurrence (Figs. 21-7 and 21-8).

Lymphatic Supply

Lymphatic channels from the testis drain into the para-aortic and interaortocaval lymph nodes. These lymphatic channels ascend within the spermatic cord after leaving the testis (Hundeiker, 1969).

Nerve Supply

Visceral innervation to the testis and epididymis arise in the renal and aortic plexuses and course alongside the gonadal vessels. This is autonomic innervation, as the testis does not have

Figure 21-8. Microsurgical view of the veins of the pampiniform plexus during varicocele ligation through a subinguinal approach.

any known somatic innervation (Mitchell, 1935). The pelvic plexus, in association with the vas deferens, offers additional gonadal afferent and efferent nerves (Rauchenwald et al, 1995). Three distinct anatomic distributions of nerves have been isolated within the spermatic cord, and are thought to be the primary contributors in men with chronic orchialgia. These include a perivascular complex, posterior periaarterial/lipomatous complex, and intracremasteric complex (Parekattil et al, 2013). Some afferent and efferent nerves cross over to the contralateral pelvic plexus (Taguchi et al, 1999). This may account for pathology in one testis impacting the function of the contralateral testis, which has been reported with varicoceles and testicular tumors. The genital branch of the genitofemoral nerve primarily supplies sensation to the parietal and visceral tunica vaginalis and the overlying scrotum. These nerves travel along the testicular artery to reach the testis. These nerves ramify within the tunica albuginea, but do not enter the seminiferous tubules. Nerves are absent from the seminiferous epithelium.

Blood-Testis Barrier

The fluid passing from the seminiferous tubules and exiting from the testis has been found to have a substantially different fluid composition than that of blood plasma or lymphatics. This suggests that compounds do not freely diffuse to and from the tubules, indicating that a barrier exists, which is known as the blood-testis barrier (Setchell and Waites, 1975). There are extremely strong, tight junctions between Sertoli cells, which provide an intracellular barrier that allows for spermatogenesis in an immune privileged site. This is the barrier known as the blood-testis barrier (Ewing et al, 1980). This accounts for the anatomic component of the blood-testis barrier. The functional component will be further discussed in Chapter 22.

Ultrasonography

Ultrasonography is the primary imaging modality used to interrogate the scrotum and its contents. Scrotal ultrasound uses high-frequency transducers (7.5 to 10 MHz), grey scale real-time techniques, as well as color flow and power Doppler. The patient is

Figure 21-9. Testis ultrasound image demonstrating rete testis (arrow).

Figure 21-10. Doppler ultrasound image of testis demonstrating spokelike radiation of testicular vessels originating from the mediastinum testis.

placed in the supine position and a coupling gel is used with the transducer probe on the scrotal skin. The normal scrotal wall is 3 to 4 mm thick and is hypoechoic. An anechoic area between the echogenic scrotal wall and testicle is commonly visualized, which represents a small amount of physiologic fluid between the visceral and parietal layers of the tunica vaginalis. The mediastinum testis is visualized posteriorly as an echogenic band parallel to the epididymis. It may have variable lengths and thicknesses dependent on each patient's physiology (Dogra et al, 2003). The echo pattern of the normal testis is fine, uniform, with a medium-level echo pattern. Sonographically, the normal testis measures approximately 5 cm × 3 cm × 2 cm (Dogra et al, 2001). Color Doppler can identify testicular vessels in the majority of patients (Spimack and Resnick, 2002). Waveforms from intratesticular arteries and testicular capsular arteries demonstrate consistently low-impedance patterns with high levels of diastolic flow. This represents the lower vascular resistance of the testis. Supratesticular arteries are also sonographically identifiable and show low-impedance waveforms from the testicular, deferential, and cremasteric arteries (Middleton et al, 1989) (Figs. 21-9 and 21-10).

EPIDIDYMIS

Gross Structure

The epididymis is a duct or tubule that is attached to the posterolateral aspect of the testis and is nearest to the testis at its upper

Figure 21-11. Testis and epididymis. A, One to three seminiferous tubules fill each compartment and drain into the rete testis in the mediastinum. Twelve to 20 efferent ductules become convoluted in the head of the epididymis and drain into a single coiled duct of the epididymis. The vas is convoluted in its first portion. B, Cross section of the testis, showing the mediastinum and septations continuous with the tunica albuginea. The parietal and visceral tunica vaginalis are confluent where the vessels and nerves enter the posterior aspect of the testis.

KEY POINTS: TESTIS

- The seminiferous tubules contain developing germ cells.
- The Leydig cells produce testosterone.
- There are three arterial supplies to the testis including the testicular artery, deferential artery, and cremasteric artery.
- Lymphatic channels from the testis drain into the para-aortic and interaortocaval lymph nodes.
- The nerves contributing to chronic orchialgia include a perivasal complex, posterior periarterial/lipomatous complex, and intracremasteric complex.
- Tight junctions between Sertoli cells comprise the anatomic component of the blood-testis barrier.
- Ultrasonography is the primary imaging modality for intra-scrotal content.

pole. Its lower pole is connected to the testis with fibrous tissue. The epididymis is comma shaped. The epididymis is tightly coiled and encapsulated within the tunica vaginalis sheath and would measure 3 to 4 m in length if stretched out (Von Lanz and Neuhaeuser, 1964; Turner et al, 1978). Septa form by extensions of the tunica vaginalis sheath into interductal spaces that divide the duct into histologically characteristic areas (Kormano and Reijonen, 1976). The three areas are characterized as the caput (head), the corpus (body), and the cauda (tail) of the epididymis. Eight to 12 ductuli efferentes from the testis comprise the caput epididymis. The caput epididymis is connected to the testis by multiple efferent ducts. The tightly coiled duct, which makes up the epididymis, is continuous with the vas deferens at the most distal portion of the cauda epididymis. Adjacent to the testis, this duct is irregularly shaped and comparatively large. The duct becomes more narrow and concentric near the junction with the ductus epididymis. The duct diameter remains unchanged throughout the corpus epididymis. The diameter of the duct enlarges and becomes irregular in shape in the cauda epididymis. The duct then progresses distally to form the vas deferens. A cystic body on the upper pole of the caput epididymis, which may be pedunculated or sessile, is known as the appendix of the epididymis (Figs. 21-11, 21-12, and 21-13).

Microanatomic Architecture

There are two primary types of cells throughout the epididymis: principal cells and basal cells (Holstein, 1969; Vendrely, 1981).

Figure 21-12. Gross microsurgical appearance of the epididymal caput and corpus.

From caput to cauda, the height of the epithelium decreases, whereas the diameter of the ductus and lumen increases. There are stereocilia that shorten progressively from the proximal to the distal epididymis. In the proximal epididymis, these stereocilia measure 120 μm in height and decrease to 50 μm in the distal epididymis. The principal cells contain elongated nuclei that are commonly clefted, and they contain one or two nucleoli. As the principal cells have absorptive and secretive functions, the apex of each of these cells contains multiple coated pits, membranous vesicles, multivesicular bodies, micropinocytic vesicles, and an extensive Golgi apparatus (Vendrely and Dadoune, 1988). There is a much larger number of principal cells in the epididymal epithelium than the number of basal cells that exist there. The basal cells are interdispersed between the principal cells. The basal cells are tear-shaped. They are positioned on the basal lamina and are 25 μm in length as they reach up toward the lumen. As opposed to the morphology of the principal cells, which varies throughout the epididymis, the basal cells' shape remains relatively consistent throughout the entirety of the

Figure 21-13. Microsurgical appearance of the epididymal duct after being stained with methylene blue.

epididymis. The basal cells are believed to be derived from macrophages and to be precursors of principal cells. There is a fair amount of variability in the nature of the epithelium of the epididymis, which is dependent on the region. There is a clear transition from a low to a high cuboidal epithelium where the rete testis and ductuli efferentes meet. The ductuli efferentes contain ciliated and nonciliated cells and the epithelium appears uneven (Holstein, 1969). The epithelium of the proximal ductuli efferentes primarily consists of nonciliated cells with extending apices thought to be for secretory function. The ciliated cells conduct sperm cells from the efferent duct to the epididymis, and they are widely dispersed throughout the epithelium (Vendrely, 1981). Junctional complexes join ciliated and nonciliated cells together at their apices, suggesting a blood-epididymis barrier (Suzuki and Nagano, 1978; Turner, 1979; Hoffer and Hinton, 1984). In the ductuli efferentes, the proximal corpus epididymis, and the distal caput epididymis there are contractile cells around the tubule in a loose, two-to-four cell-deep layer (Baumgarten et al, 1971). Nexuslike junctions connect these contractile cells to one another and each cell contains myofilaments. These cells are larger and appear like thin smooth muscle cells in the distal corpus epididymis, where they have fewer intracellular junctions. Thick smooth muscle cells are found in the cauda epididymis. The smooth muscle cells are organized in three layers. The cells have a longitudinal orientation in the two outer layers and a circular orientation in the central layer. The thickness of the distal contractile layer progressively increases as it forms the vas deferens.

Arterial Supply

A branch of the testicular artery supplies the caput and corpus epididymis. This arterial branch then further divides to supply the superior and inferior epididymal branches (Macmillan, 1954). The deferential artery also provides vascular supply to the epididymis. Branches from the deferential artery supply the cauda epididymis. As with the testis, the deferential and cremasteric arteries also supply the epididymis and can compensate for a ligated testicular artery. The connective tissue sheaths forming septa in the epididymis are the entry points for arterial supply within the epididymis. The coiled vessels ultimately straighten to form the microvascular bed within the epididymis (Kormano and Reijonen, 1976). The density of the microvasculature decreases progressively, with the caput containing the highest density of microvasculature and the more distal segments containing lower density (Clavert et al, 1981).

Venous Drainage

The corpus and cauda epididymis have their venous drainage through the vena marginalis of Haberer, draining into the

pampiniform plexus via the vena marginalis testis, or through deferential or cremasteric veins (Macmillan, 1954).

Lymphatic Supply

Similar to that of the testis, the caput and corpus epididymis have their lymphatic drainage through channels that travel with the internal spermatic vein, draining to the preaortic nodes. Lymphatic channels from the cauda epididymis join those leaving the vas deferens to drain ultimately into the external iliac nodes.

Nerve Supply

The superior portion of the hypogastric plexus and the pelvic plexus yield the intermediate and inferior spermatic nerves, respectively, which innervate the epididymis (Mitchell, 1935). Fibers from the sympathetic nervous system sparsely innervate the proximal portion of the epididymis as well as the ductuli efferentes (Baumgarten and Holstein, 1967; Baumgarten et al, 1971). These fibers form a peritubular plexus that is adjacent to the vasculature. The corpus epididymis includes sparse numbers of nerve fibers, and the density of nerve fibers increases progressively traveling toward the cauda epididymis. The density of fibers begins to increase at the midcorpus of the epididymis and the progressive increase in fibers is associated with the progressive proliferation of smooth muscle cells (Baumgarten et al, 1971).

Ultrasonography

The epididymis can be visualized ultrasonographically in its posterolateral position to the testis. The epididymis appears either hyperechoic or isoechoic in comparison to the testis (Spimak and Resnick, 2002). Compared to the testis, the caput epididymis is typically isoechoic, the corpus epididymis is hypoechoic, and the vas deferens is anechoic (Puttemans et al, 2006). The epididymis is typically homogeneous, with well-defined echoes surrounding the epididymis that represent the fascial lining (Black and Patel, 1996). By sonographic measurement, the normal caput epididymis diameter measures between 10 mm and 12 mm and the normal corpus epididymis measures between 2 mm and 5 mm (Pezzella et al, 2013). In 98% of men, the caput epididymis is above the upper pole of the testis, with the corpus epididymis typically lateral to the testis. The corpus epididymis is posterior to the body of the testis in 6% of men. The epididymis is inverted with the caput epididymis inferior to the lower pole of the testis in 2.4% of men (Puttemans et al, 2006). The appendix epididymis can be identified as an isoechoic structure attached to the caput epididymis (Black and Patel, 1996). Vascular flow is detectable with pulsed Doppler and color Doppler in all regions of the epididymis in nonpathologic states. The mean resistive index throughout the normal epididymis is approximately 0.55 (Keener et al, 1997) (Fig. 21-14).

KEY POINTS: EPIDIDYMIS

- The two primary cell types throughout the epididymis are principal cells and basal cells.
- The arterial supply to the caput and corpus epididymis is from a branch of the testicular artery and the cauda is supplied from deferential arterial branches.

VAS DEFERENS

Gross Structure

The vas deferens, also known as the ductus deferens, extends from the distal end of the cauda epididymis. It is tubular and its embryologic origin is the mesonephric (wolffian) duct. The vas deferens is tortuous for 2 to 3 cm as it leaves the epididymis (the convoluted vas deferens). From the cauda epididymis to its termination at the

Figure 21-14. Ultrasound imaging of the caput epididymis, which appears hyperechoic to the testis and is at the right of the testis on this image.

Figure 21-15. Microsurgical appearance of the transected vas deferens at the time of vasovasostomy.

ejaculatory duct, the vas deferens measures between 30 and 35 cm in length. The vas deferens travels posteriorly along the spermatic cord, behind the vessels in the cord. The vas deferens passes through the inguinal canal and enters the pelvis lateral to the epigastric vessels. On entering the pelvis, after passing through the internal inguinal ring, the vas deferens separates from the testicular vessels. The vas deferens ultimately reaches the posterior base of the prostate after traveling medial to the pelvic sidewall. The vas deferens is compartmentalized into five different regions. The first is the epididymal segment within the tunica vaginalis, which does not have a sheath. The second is the segment within the scrotum. The third segment is that within the inguinal canal. The fourth is the retroperitoneal segment, and the fifth is the ampulla of the vas deferens (Lich et al, 1978). The lumen of the vas deferens ranges between 0.2 and 0.7 mm in diameter, depending on the segment. The outer diameter of the vas deferens ranges between 1.5 and 2.7 mm (Middleton et al, 2009) (Figs. 21-15 and 21-16).

Microanatomic Architecture

There is an outer adventitial connective tissue layer surrounding the vas deferens that contains blood vessels and small nerves. Within

Figure 21-16. Laparoscopic visualization of the vas deferens.

this connective tissue layer, smooth muscle cells comprise the thick wall of the vas deferens. These smooth muscle cells are organized as an inner and outer longitudinal layer, a middle circular layer, and a pseudostratified columnar epithelial layer with nonmotile stereocilia as the inner lining, known as its mucosa (Neaves, 1975; Paniagua et al, 1981). The epithelial cell height decreases progressively throughout the length of the vas deferens from the testis to the seminal vesicle. There are three types of tall, thin columnar cells, as well as basal cells, comprising the pseudostratified epithelium of the vas deferens (Hoffer, 1976; Paniagua et al, 1981). Principal cells, pencil cells, and mitochondria-rich cells comprise the columnar cells that extend from the epithelial base to the lumen. The columnar cells have irregularly shaped convoluted nuclei and have stereocilia. In the proximal vas deferens, principal cells are the predominant cell type. Traveling more distally throughout the vas deferens, more pencil cells and mitochondria-rich cells are present. The muscular layer of the vas deferens progressively decreases from proximal to distal.

Arterial Supply

The superior vesical artery gives off the deferential artery, which supplies the vas deferens (Sjostrand, 1965).

Venous Drainage

The venous drainage of the scrotal vas deferens is via the deferential vein, which drains into the pampiniform plexus. The pelvic vas deferens' venous drainage is to the pelvic venous plexus.

Lymphatic Supply

Lymphatic drainage from the vas deferens travels to the external and internal iliac nodes.

Nerve Supply

The vas deferens receives sympathetic and parasympathetic innervation (Sjostrand, 1965). The sympathetic adrenergic nerves travel via the presacral nerve from the hypogastric nerve (Batra and Lardner, 1976; McConnell et al, 1982). All three layers of the vas deferens tunica muscularis contain adrenergic fibers, but the greatest density of these nerve fibers is found in the outer longitudinal layer (McConnell et al, 1982). Other types of neurotransmitters have been identified within neurons such as somatostatin, galanin, enkephalin, neuropeptide Y, vasoactive intestinal peptide, and nitric oxide. The function of these neurotransmitters in the vas deferens is not well understood (Dixon et al, 1998).

Vasogram

The vasogram was previously considered to be the radiographic test of choice to evaluate the prostate, ejaculatory duct, and seminal vesicles in the infertile male. The vasogram has been replaced by transrectal ultrasonography for the most part, and the vasogram is only used in conjunction with reconstructive surgery ([Honig, 1994](#)).

KEY POINTS: VAS DEFERENS

- The lumen of the vas deferens ranges between 0.2 and 0.7 mm in diameter, depending on the segment.
- The superior vesical artery gives off the deferential artery, which supplies the vas deferens.
- A vasogram should only be performed in conjunction with reconstructive surgery.

SEMINAL VESICLES AND EJACULATORY DUCTS

Gross Structure

The seminal vesicles are paired, viscous organs that are positioned posterior to the bladder and prostate. The seminal vesicle is a lateral outpouching of the vas deferens. It has the capacity for 3 to 4 mL of volume and the nonobstructed seminal vesicle typically measures 5 to 7 cm in length and 1.5 cm in width. The seminal vesicle is a single tube that is highly coiled, and it forms several outpouchings and would measure 15 cm in length if stretched out. The joining of the seminal vesicle with the vas deferens creates the ejaculatory duct. The smooth muscle sheaths from the seminal vesicle and the vas deferens combine with the capsule of the prostate at the prostatic base. The seminal vesicles' excretory duct joins the duct of the ampullary vas deferens as it enters the prostate.

The ejaculatory ducts are positioned at the junction of the vas deferens and the seminal vesicle. The ejaculatory ducts are paired visceral organs. **They ultimately empty through the verumontanum into the prostatic urethra.** The ejaculatory duct is divided into three distinct anatomic regions. These include the extraprostatic region (proximal), intraprostatic region (mid), and the distal region, which joins the lateral aspect of the verumontanum to empty into the prostatic urethra ([Nguyen et al, 1996](#)). In contrast to the first two regions, the third distal region is not surrounded by an outer muscular layer and does not form an anatomic sphincter at the ejaculatory duct orifice at the verumontanum ([Nguyen et al, 1996](#)).

Microanatomic Architecture

The seminal vesicle has a columnar epithelium with goblet cells. The seminal vesicle tube is surrounded by a thin layer of smooth muscle cells, which is enveloped by a loose adventitia. The three layers comprising the tubule of the seminal vesicle include an inner mucous membrane, a collagenous middle layer, and the outer circular and longitudinal muscle layers. The muscle layers account for 80% of the thickness of the wall of the seminal vesicle ([Nguyen et al, 1996](#)). The thin, folded mucosa of the seminal vesicle is comprised of nonciliated, pseudostratified cuboidal or columnar cells. The ejaculatory ducts have similar microanatomic architecture to the seminal vesicles, but they do not have the outer circular muscle layer that is found in the seminal vesicle ([Nguyen et al, 1996](#)). The inner epithelial layer of the ejaculatory duct is composed of simple and pseudostratified columnar cells in a folded pattern.

Arterial Supply

The arterial supply to the seminal vesicle originates from the superior vesical artery, which branches into the vesiculodeferential

artery. The vesiculodeferential artery supplies the anterior surface of the seminal vesicle in proximity to its tip. The internal iliac artery and inferior vesical artery provide additional arterial supply to the seminal vesicle via the prostatovesicular branch ([Clegg, 1955](#)). Variations of arterial supply include the prostatovesicular branch originating from the pudendal artery or the superior vesical artery. Arterial supply to the ejaculatory duct arises from branches of the inferior vesical artery.

Venous Drainage

The venous drainage of the seminal vesicle follows the arterial supply draining through the vesiculodeferential veins and the inferior vesical plexus to the pelvic venous plexus.

Lymphatic Supply

The lymphatic drainage from the seminal vesicle is to the internal iliac nodes ([Mawhinney and Tarry, 1991](#)).

Nerve Supply

Seminal vesicle parasympathetic innervation originates from the pelvic plexus with the sympathetic nervous system contributing fibers from the hypogastric nerves and the superior lumbar nerves ([Kolbeck and Steers, 1993](#)). The pelvic plexus innervates the ejaculatory ducts.

Transrectal Ultrasonography

The seminal vesicles can be imaged by transrectal ultrasonography, as they are positioned posteriorly at the base of the prostate. The seminal vesicles appear hypoechoic, compared to the prostate, and are crescent-shaped, paired, and symmetrical. The normal seminal vesicle measures 2 cm in width and 4.5 to 5.5 cm in length. They can be visualized as oriented horizontally in the transverse plane. Hypoechoic fatty tissue can be seen separating the seminal vesicles from the base of the prostate. The ejaculatory ducts may occasionally be seen by transrectal ultrasonography and they appear hypoechoic as they enter the prostate posteriorly.

Computed Tomography

Computed tomography (CT) can image the seminal vesicles. The mean measurements by CT of the seminal vesicles are 3 cm in length and 1.5 cm in width. No significant change is seen by CT in seminal vesicle length on the basis of age. However, the width of the seminal vesicle is smaller in men of increasing age. The pudendal venous plexus can be identified by CT as small punctuate densities along the lateral aspect of the seminal vesicle ([Silverman et al, 1985](#)).

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) of the normal seminal vesicles demonstrate similar signal intensity to that of the bladder or muscle on T1 imaging. The seminal vesicles demonstrate a higher signal intensity than the surrounding fat on T2 imaging ([King et al, 1989](#); [Secaf et al, 1991](#)) (Fig. 21-17; also see Fig. 21-16).

KEY POINTS: SEMINAL VESICLES AND EJACULATORY DUCTS

- The nonobstructed seminal vesicle typically measures 5 to 7 cm in length and 1.5 cm in width.
- The ejaculatory ducts empty through the verumontanum into the prostatic urethra.
- Transrectal ultrasound, CT, and MRI can image the seminal vesicles.

Figure 21-17. Endoscopic view into the os of the ejaculatory duct transurethrally.

PROSTATE

Gross Structure

The normal prostate gland is ovoid in shape and measures 3 cm in length, 4 cm in width, and 2 cm in depth; it has a weight of 18 to 20 g. It is homologous to the Skene glands in females. The prostate is composed of glandular elements and fibromuscular stroma. The prostate is positioned just inferior to the bladder. The prostatic urethra travels through the prostate gland. The base of the prostate is at the bladder-prostate junction and the narrowed apex is the most inferior portion of the prostate gland, reaching the urogenital diaphragm. The prostate is palpable approximately 4 cm from the anus on digital rectal examination. **The apex of the prostate is continuous with the striated urethral sphincter.** The prostate is comprised of an anterior surface, a posterior surface, and lateral surfaces, and these are in relationship to the prostatic urethra traversing the prostate. A collagen, elastin, and smooth muscle capsule envelops the prostate. The capsule measures 0.5 mm in thickness posteriorly and laterally on average. There is no true prostatic capsule at the apex of the prostate, where normal prostate glands are seen blending into the striated muscle of the urethral sphincter. Similarly, there is no true capsule at the base separating the prostate from the bladder, where the detrusor muscle's outer longitudinal fibers fuse with the fibromuscular capsule of the prostate (Epstein, 1989). The prostate capsule blends with the continuation of the endopelvic fascia on the anterior and anterolateral aspects of the prostate. The prostate is fixed to the pubic bone anteriorly by the puboprostatic ligaments near the apex of the prostate. The superficial branch of the dorsal vein is positioned in the retropubic fat outside the prostatic fascia. It drains into the dorsal vein complex. The levator ani's pubococcygeal portion hugs the lateral aspects of the prostate and is related to its overlying endopelvic fascia. The prostate capsule and the pelvic fascia separate below the parietal and visceral endopelvic fascia juncture (arcus tendineus fascia pelvis). Fatty, areolar tissue and the lateral branches of the dorsal vein complex take up the space of this separation between the prostate capsule and the pelvic fascia. **The cavernosal nerves travel within the parietal pelvic fascia, also known as the lateral prostatic fascia, posterolateral to the prostate.** As more anatomic attention has been taken with higher-magnification robotic techniques at the time of radical prostatectomy, the lateral prostatic fascia has been defined in greater detail in an effort to preserve the cavernosal nerves. Nerve bundles have been identified traveling along the prostate laterally and anterior to the previously defined neurovascular bundle (Eichelberg et al, 2007; Raychaudhuri and Cahill, 2008) (Fig. 21-18).

Figure 21-18. Cross section of prostate with prostatic fascial layers outlined, including the lateral prostatic fascia (LPF), endopelvic fascia (EPF), levator ani fascia (LAF), Denonvilliers fascia (DF), anterior lamina of Denonvilliers fascia (ADF), posterior lamina of Denonvilliers fascia (PDF), neurovascular bundle (NVB), and lateral nerves (N). (From Walz J, Graefen M, Huland H. Basic principles of anatomy for optimal surgical treatment of prostate cancer. *World J Urol* 2007;25:31–8.)

The prostate has been divided into distinct anatomic zones. These zones can be identified with transrectal ultrasonography. The transition zone is the smallest of the zones of the prostate. The ducts of the transition zone begin at the angle dividing the preprostatic and the prostatic urethra, and they travel beneath the preprostatic sphincter to course along its lateral and posterior sides. The transition zone comprises 5% to 10% of the glandular tissue of the normal prostate. The transition zone is separated from the rest of the glandular compartments of the prostate by a distinct fibromuscular band. Benign prostatic hyperplasia most commonly occurs in the transition zone. The central zone ducts are positioned circumferentially, surrounding the openings of the ejaculatory ducts. This zone expands toward the base of the bladder, surrounding the ejaculatory ducts, in the shape of a cone. The central zone comprises 25% of the glandular tissue of the prostate. The glands of the central zone are thought to be of wolffian duct origin, as they differ immunohistochemically and structurally from the other glands of the prostate (McNeal, 1988). **The peripheral zone of the prostate is the largest zone. Seventy percent of the glandular tissue of the prostate is comprised of the peripheral zone.** The peripheral zone makes up the posterior and lateral aspects of the prostate gland. The ducts of the peripheral zone drain into the prostatic sinus along the entire length of the post-sphincteric prostatic urethra. Seventy percent of prostate cancers are found in the peripheral zone. The nonglandular anterior fibromuscular stroma is found extending from the bladder neck to the striated sphincter, and it may comprise up to one third of the mass of the prostate. It is composed of collagen, smooth and striated muscle, and elastin. It is anatomically continuous with the anterior visceral fascia, the anterior preprostatic sphincter, and the prostatic capsule.

The prostate is also compartmentalized clinically, based on digital rectal examination and cystoscopic appearance. A central sulcus divides the two lateral lobes of the prostate and a middle lobe. The middle lobe may become hyperplastic and may extend into the bladder neck with age (Fig. 21-19).

Figure 21-19. Zonal anatomy of the prostate as described by McNeal (1988). The transition zone surrounds the urethra proximal to the ejaculatory ducts. The central zone surrounds the ejaculatory ducts and projects under the bladder base. The peripheral zone constitutes the bulk of the apical, posterior, and lateral aspects of the prostate. The anterior fibromuscular stroma extends from the bladder neck to the striated urethral sphincter. (© 1990, Baylor College of Medicine.)

Microanatomic Architecture

Seventy percent of the prostate's composition is glandular elements, whereas 30% is made up of fibromuscular stroma. The epithelial cells of the prostate glands are cuboidal or columnar. These secretory epithelial cells are terminally differentiated, have a low proliferative index, and measure 10 to 20 μm in height (De Marzo et al, 1998). These epithelial cells have abundant secretory granules and are organized in rows with their apices projecting into the lumen and their bases attached to a basement membrane (Knox et al, 1994). The nuclei of the cells are at their base, below the Golgi apparatus. The luminal apices have microvilli. The epithelial cells line the periphery of the acinus and secrete into the acinus, which drain into ducts to the urethra ultimately. The tubuloalveolar glands have simple branching patterns. Flattened, undifferentiated basal cells line each acinus beneath the epithelial cells. A thin layer of connective tissue and stromal smooth muscle surrounds each acinus. The secretory cells have scattered, terminally differentiated, non-proliferating neuroendocrine cells between them. Two types of neuroendocrine cells have been identified in the prostate. One is a closed cell with dendritelike processes that extend toward epithelial cells and basal cells in its proximity. The other type of neuroendocrine cell type seen is an open one with microvilli extending into the lumen (di Sant'Agnese and De Mesy Jensen, 1984; Abrahamsson, 1999; Vashchenko and Abrahamsson, 2005). The stroma is composed of smooth muscle, which is rich in α -actin, myosin, and desmin, and it is also composed of collagen and is continuous with the prostatic capsule. At the junction of the prostate gland, the prostatic urethra, the transitional cells of the prostatic urethra's epithelium, may extend into prostatic ducts. The preprostatic (internal urethral) sphincter encloses the small periurethral prostatic glands without periglandular smooth muscle, and these glands are positioned between fibers of longitudinal smooth muscle. Posterior to the prostate, microscopic smooth muscle bands fuse with Denonvilliers fascia after extending from the posterior aspect of the prostatic capsule. There is a plane of loose, areolar tissue between Denonvilliers fascia and the rectum.

Figure 21-20. Arterial supply of the prostate. (Modified from Flocks RH. The arterial distribution within the prostate gland: its role in transurethral prostatic resection. J Urol 1937;37:527.)

Arterial Supply

The inferior vesical artery is the typical arterial supply to the prostate. The inferior vesical artery branches into urethral arteries that enter the prostatovesical junction posterolaterally and course in a perpendicular route to the urethra. They travel toward the bladder neck with the largest branches posteriorly, approaching the bladder neck in the one o'clock to five o'clock positions and the seven o'clock to eleven o'clock positions. They then supply the urethra after making a caudal turn to run parallel to the urethra. These branches supply the urethra, the periurethral glands, and the transition zone of the prostate (Flocks, 1937). The inferior vesical artery also branches into the capsular artery. The capsular artery yields small branches that supply the anterior prostatic capsule. The capsular branches enter the prostate at 90-degree angles and provide arterial supply to the glandular tissues, coursing along the reticular bands of the stroma. The majority of the inferior vesical artery travels posterolateral to the prostate to form the neurovascular bundles coursing with the cavernous nerves, terminating at the pelvic diaphragm. Branches from the internal pudendal artery and the middle rectal (hemorrhoidal) artery also contribute a supply to the prostate (Fig. 21-20).

Venous Drainage

The prostate includes abundant venous drainage through the periprostatic plexus. The periprostatic plexus anastomoses with the deep dorsal vein of the penis and the internal iliac (hypogastric) veins.

Lymphatic Drainage

The obturator and internal iliac nodes are the primary sites of lymphatic drainage from the prostate. The presacral group or, infrequently, the external iliac nodes may receive a small portion of the initial lymphatic drainage.

Nerve Supply

The cavernous nerves provide sympathetic and parasympathetic innervation to the prostate from the pelvic plexus. Innervations to the glandular and stromal elements of the prostate are found traveling with branches of the capsular artery. Sympathetic fibers innervate the smooth muscle of the capsule and stroma for contraction. The parasympathetic nerves promote secretory function by terminating in the acini. Prostate smooth muscle relaxation may be affected by peptidergic and nitric oxide synthase-containing neurons that have been identified in the prostate (Burnett, 1995). The pelvic plexuses carry afferent neurons from the prostate to the pelvic and thoracolumbar spinal centers.

Transrectal Ultrasonography of the Prostate

Transrectal ultrasonography of the prostate provides multiple diagnostic utilities including assessing prostate volume, locating focal abnormalities, assessing patients with infertility with suspicion of obstruction, and guiding prostate biopsies. The prostate is imaged with biplane, multiplane, and end-fire endorectal transducer probes with a frequency ranging from 6 to 8 MHz. The patient should be positioned either in the lateral decubitus or the dorsal lithotomy position, and a well-lubricated transrectal probe is gently passed into rectum above the anal verge. The prostate and seminal vesicles should be systematically examined in the longitudinal and transverse orientations. Pertinent images should be recorded and labeled (Terris et al, 1992). The normal prostate has a stipple grey echogenicity and appears homogeneous. The capsule appears echogenic, continuous, and well defined. The zonal compartments can be identified. A distinct layer of echogenic fibrous tissue separates the zones. The prostate presents a semilunar shape and appears symmetrical in the transverse orientation. The peripheral zone has a homogeneous, fine echo pattern. The periurethral tissue is centrally positioned and appears hypoechoic. The relation of the prostate to the surrounding structures such as the seminal vesicles, bladder neck, and prostatic urethra can be identified in the longitudinal orientation. The urethra will appear curved within the central portion of the prostate.

The prostate volume can be measured using transrectal ultrasonography with an accuracy of within 5% of its true weight (Hastak et al, 1982). Transverse and longitudinal orientations are used to measure the length, width, and height of the prostate. An ellipsoid formula is then used to estimate the volume of the prostate: $\text{Volume} = \frac{4}{3}\pi \times \text{length} \times \text{width} \times \text{height}$ (Roehrborn et al, 1986) (Fig. 21-21).

Magnetic Resonance Imaging of the Prostate

MRI of the prostate has been used to provide high-quality, clear images. MRI's direct multiplanar imaging has allowed for detailed demonstration of prostate anatomy (Dooms and Hricak, 1986). Zonal anatomy can be more clearly demonstrated by MRI using 0.5 cm slices. The peripheral zone showed higher signal intensity than the other zones and can be well visualized in the coronal, sagittal, and transverse planes. The central zone was well visualized in the coronal and sagittal planes and was of low signal intensity.

Figure 21-21. Transrectal ultrasound of the prostate demonstrating the peripheral zone (1) and the transition zone (2).

Figure 21-22. Axial T2-weighted magnetic resonance image of the male pelvis through the prostate gland and adjacent structures. 1, Urinary bladder; 2, lateral lobes of prostate; 3, verumontanum; 4, striated urethral sphincter; 5, inferior pubic ramus; 6, corpus spongiosum in cross section; 7, external iliac artery.

The transition zone showed similar MR parameters to the central zone (Hricak et al, 1987). Zonal anatomy is best demonstrated by T2-weighted images (Gevenois et al, 1990). Using a specific pulse sequence, the periprostatic venous plexus can be imaged (Poon et al, 1985). The endorectal surface coil has been used to enhance resolution (Schnall and Pollack, 1990). The use of MRI of the prostate has become more frequent for use with pathologic processes (Fig. 21-22).

URETHRA

The urethra is contained within the vascular corpus spongiosum and the glans penis. The normal urethral diameter is 8 to 9 mm. Anatomists have organized the urethra into multiple different

KEY POINTS: PROSTATE

- The normal prostate gland measures 3 cm in length, 4 cm in width, and 2 cm in depth, and it has a weight of 18 to 20 g.
- There is no true prostatic capsule at the apex of the prostate.
- The cavernosal nerves travel within the lateral prostatic fascia, posterolateral to the prostate.
- Benign prostatic hyperplasia most commonly occurs in the transition zone of the prostate.
- A total of 70% of the glandular tissue of the prostate is comprised of the peripheral zone and 70% of prostate cancers are found in the peripheral zone.
- Seventy percent of the prostate's composition includes glandular elements, whereas 30% is made up of fibromuscular stroma.
- The inferior vesical artery is the typical arterial supply to the prostate.
- The periprostatic plexus anastomoses with the deep dorsal vein of the penis and the internal iliac (hypogastric) veins.
- The obturator and internal iliac nodes are the primary sites of lymphatic drainage from the prostate.
- Transrectal ultrasonography of the prostate is useful for assessing prostate volume, locating focal abnormalities, assessing patients with infertility with suspicion of obstruction, and guiding prostate biopsies.

segmental divisions. It has been categorized in two broad segments: the anterior urethra and the posterior urethra. The **anterior urethra** begins at the perineal membrane and continues distally to the urethral meatus. The **posterior urethra** begins distal to the bladder neck and the transition to the anterior urethra is made at the perineal membrane. The segments have been further divided to characterize urethral anatomy more precisely. The **urethral epithelium** is transitional in type until the urethral epithelium becomes squamous where it traverses the glans penis. The submucosa contains smooth muscle, connective tissue, and elastic tissue. The glands of Littre are in the submucosa and their ducts empty into the urethral lumen. The arterial supply to the urethra is from the internal pudendal artery whose bulbourethral branches supply the urethra, the corpus spongiosum, as well as the glans penis. The venous drainage from the urethra drains to the pudendal plexus, which drains into the internal pudendal vein. The lymphatics from the urethra drain to the internal iliac (hypogastric) and common iliac nodes (Fig. 21-23).

Prostatic Urethra

The prostatic urethra travels the length of the prostate and is in greater proximity to the anterior surface of the prostate. A urethral crest extends inward from the posterior midline of the prostatic urethra and is present throughout the length of the prostatic urethra. This urethral crest is no longer present at the level of the striated sphincter. All glandular elements of the prostate drain into prostatic sinuses, which are positioned on either side of the urethral crest (McNeal, 1972). The urothelium of the prostatic urethra is made up of transitional epithelial cells. This transitional urothelium may extend into prostatic ducts. An angle at the mid-point of the prostatic urethra turns 35 degrees anteriorly and separates the prostatic urethra into anatomically and functionally distinct segments. These are termed the preprostatic (proximal) and prostatic (distal) segments of the prostatic urethra. This angle may range from zero to 90 degrees depending on variable anatomy (McNeal, 1972, 1988). All glandular elements of the prostate open into the prostatic urethra past the urethral angle. The **verumontanum** is formed by the widening and protrusion of the urethral crest from the posterior wall. The **prostatic utricle orifice** appears like a slit at the apex of the verumontanum. The utricle orifice is cystoscopically visible and measures 6 mm. The **prostatic utricle** is a müllerian remnant. The two small openings of the ejaculatory ducts are located on either side of the utricular orifice. After forming

Figure 21-23. Posterior wall of the male urethra. (From Anson BJ, McVay CB. *Surgical anatomy*. 6th ed. Philadelphia: Saunders; 1984. p. 833.)

at the juncture of the vas deferens and seminal vesicles, the ejaculatory ducts travel approximately 2 cm through the prostate surrounded by circular smooth muscle, until they finally open into the distal prostatic urethra. The preprostatic sphincter is made up of thickened circular smooth muscle, synonymous with the internal urethral sphincter in the proximal segment. The prostatic segment is innervated by motor somatic fibers with an absence of any autonomic innervation (Figs. 21-24 and 21-25).

Membranous Urethra

On average the membranous urethra measures 2 to 2.5 cm in length and spans between the prostatic apex and the perineal membrane (Myers, 1991). A thin, smooth muscle layer spans across the membranous urethra. An outer layer of circularly arranged striated muscle in the shape of a horseshoe near the prostatic apex is found on the anterior surface of the urethra. The striated muscle reaches from the base of the bladder and the anterior aspect of the prostate extending the complete length of the membranous urethra. This signet ring-shaped striated sphincter is broad based and narrows as it courses through the urogenital hiatus of the levator ani to reach the prostatic apex. The posterior portion of the striated sphincter inserts into the perineal body throughout its length (Strasser et al, 1998). The striated sphincter is anterior to the dorsal vein complex and lateral to the levator ani. The band of fibrous tissue that suspends the urethra from the pubis anteriorly and that forms the suspensory ligament of the penis posteriorly, is made up of connective tissue from deep within the anterior and lateral walls. The striated sphincter's lumen consists of a pseudostratified columnar epithelium. There is a vascular submucosa that is surrounded by

Figure 21-24. Cystoscopic appearance of the verumontanum. (Courtesy David Leavitt, MD.)

Figure 21-25. Cystoscopic appearance of the bladder neck. (Courtesy David Leavitt, MD.)

the longitudinal and circular urethral smooth muscle, which is the intrinsic component of the external sphincter (Raz et al, 1972). The pudendal nerve supplies innervation to the striated sphincter (Tanagho et al, 1982). A branch of the sacral plexus that travels along the surface of the levator ani provides another source of somatic innervation to the sphincter (Hollabaugh et al, 1997). The cavernous nerves are believed to supply autonomic innervation to the intrinsic smooth muscle of the membranous urethra (Steiner et al, 1991). The urethral stroma contains longitudinally organized collagen fibers and elastin fibers (Hickey et al, 1982). Lymphatic drainage from the membranous urethra travels in front of the prostate to join lymphatic channels draining the anteroinferior bladder. These channels terminate in the anterior or medial retrofemoral nodes and the middle node of the medial group of the external iliac nodes. Innervation is solely by motor somatic fibers without autonomic innervation. The ventral root of S3, with some contribution from S2, provides the somatic supply. The supply branches to the pelvic (splanchnic) nerve and passes to the pelvic (inferior hypogastric) plexus. Sensory innervation from the striated sphincter travels through the pudendal nerves via S2, and to a lesser extent S3, to travel to the node of Onuf centrally (Fig. 21-26).

Penile Urethra

The penile urethra, also known as the pendulous urethra and the spongy urethra, as it is surrounded by the corpus spongiosum,

comprises the urethra distal to the membranous urethra. The urethra is often subdivided even further at the junction of the membranous and penile urethra, and is termed the bulbomembranous urethra. This region comprises a 2-cm length of urethra within the urogenital diaphragm as well as being within the striated urethral sphincter and the first few proximal centimeters of the bulbous urethra, just distal to the sphincter within the penile bulb. The bulbospongy urethra begins a few centimeters distal to the membranous urethra and extends distally to the level of the suspensory ligament. The lumen widens to form the urethral bulb. The bulbourethral glands, also known as Cowper glands, empty into this region at the three o'clock and nine o'clock positions. The bulbourethral glands themselves are located more proximally on either side of the membranous urethra. The penile urethra measures approximately 15 cm in length in its entirety from the suspensory ligament to the meatus. It is positioned more dorsally than ventrally within the corpus spongiosum. The bulb and the fossa navicularis are the two segments of urethral lumen widening; otherwise the luminal diameter is relatively consistent throughout. The mucosa of the penile urethra includes a transitional epithelium until it reaches the fossa navicularis. The muscle layer is made up of an inner longitudinal, a middle circular, and an inconsistently characterized outer longitudinal stratum. The glands of Littre are composed of small mucus-secreting cells that lubricate the urethra before ejaculation, and they empty into orifices on the posterior wall of the penile urethra. The glands of Littre are rich in goblet cells and enter the spongy tissue between the vascular spaces and the trabeculae. **The penile urethra receives arterial supply from a branch of the internal pudendal artery, which enters at the level of the penile bulb, and is known as the bulbourethral artery.** Venous drainage of the bulbar urethra is by bulbar veins that drain into the prostatic plexus, which is the internal pudendal vein. The penile urethral lymphatics drain through a lymphatic network that is associated with the mucous membrane. These lymphatic channels course longitudinally but anastomose transversely and obliquely. The lymphatic channels drain proximally into trunks at the bulbomembranous urethra. The bulbomembranous lymphatic drainage may be variable. Some lymphatic drainage travels along the urethral artery or artery of the bulb, whereas others drain to the medial retrofemoral node after traveling behind the symphysis pubis. The penile urethral sensory innervation runs through submucosal axons that pass centrally through the dorsal nerve of the penis (Fig. 21-27).

Fossa Navicularis

The glanular portion of the urethra is known as the fossa navicularis, where its caliber dilates when compared to the urethra proximal to the fossa navicularis. It narrows again at the urethral meatus. **Unlike the transitional epithelium of the remainder of the urethra, the urethral mucosa that traverses the glans penis is a**

Figure 21-27. Cystoscopic appearance of the bulbar urethra. (Courtesy David Leavitt, MD.)

Figure 21-28. Cystoscopic appearance of the fossa navicularis.

squamous epithelium. These cells become keratinized near the meatus. The epithelium is separated from the smooth muscle of the spongy tissue by loose connective tissue, and a muscularis mucosa is absent. There are multiple pockets on the dorsal and lateral surfaces of the fossa navicularis. The lacuna magna (Morgagni) is a large pocket opening on the roof of the fossa navicularis (Figs. 21-28, 21-29, and 21-30).

KEY POINTS: URETHRA

- The urethra is contained within the corpus spongiosum and the glans penis.
- The anterior urethra begins at the perineal membrane and continues distally to the urethral meatus.
- The posterior urethra begins distal to the bladder neck and the transition to anterior urethra is made at the perineal membrane.
- The urethral epithelium is transitional in type until the urethral epithelium becomes squamous where it traverses the glans penis at the fossa navicularis.
- The arterial supply to the urethra is from the internal pudendal artery whose bulbourethral branches supply the urethra, the corpus spongiosum, and glans penis.
- The verumontanum is formed by the widening and protrusion of the urethral crest from the posterior wall.
- The prostatic utricle (müllerian remnants) orifice appears like a slit at the apex of the verumontanum.

PENIS

Structure

The gross structures of the penis can be divided into distinct anatomic compartments. The paired corpora cavernosa, which are the erectile bodies, prolongate proximally as the crus and attach to the pubic arch. The urethra travels through the corpus spongiosum, with its proximal segment known as the bulb. The glans

penis is an expansion of the corpus spongiosum. The superior surface of the penis during erection is known as the dorsum and the inferior surface during erection, containing the urethra, is known as the ventrum. The major portion of the body of the penis is formed by the corpora cavernosa as they join beneath the pubis (penile hilum). A **septum separates the corpora cavernosa but is permeable distally to allow for free communication between their vascular spaces.** The tunica albuginea is the tough connective tissue layer that envelops the corpora cavernosa and is primarily collagenous. With erection, the outer longitudinal layers and inner circular fibers of the tunica albuginea are tightly stretched, and in the flaccid state they form an undulating meshwork (Goldstein et al, 1982). Smooth muscle bundles traversing the corpora cavernosa form endothelial-lined cavernous sinuses. Myoendothelial junctions, which are cellular extensions through the internal elastic lamina, have been identified as connecting the vascular smooth muscle cells to the endothelial cells. Gap junctions have been identified at the point of cell-to-cell contact in the myoendothelial junction (Kavoussi et al, 2010). The corpus spongiosum tapers and

travels ventrally to the corpora cavernosa, distal to the bulb. The glans penis is the most distal expansion of the corpus spongiosum. The shaft of the penis and the base of the glans are separated by the corona. The corpora cavernosa are surrounded by Buck fascia dorsally. Buck fascia splits to surround the corpus spongiosum ventrally. The fundiform ligament of the penis is composed of collagenous and elastic fibers from the rectus sheath blending with and surrounding Buck fascia. The suspensory ligament of the penis is made up of deeper fibers from the pubis. Deep to the muscles of the corpora cavernosa, the tunica albuginea and the Buck fascia fuse (Uhlenhuth et al, 1949). Buck fascia joins the base of the glans at the corona distally. The penile shaft skin is very elastic and its only glandular elements are the smegma-producing glands, located at the base of the corona. The penile skin is very mobile as its dartos fascia backing is very loosely attached to Buck fascia. In uncircumcised men, the prepuce (foreskin) is the penile skin as it folds over the glans and attaches below the corona. The glans penis skin is immobile as it is attached to the tunica albuginea below it (Figs. 21-31 and 21-32).

Figure 21-31. Cross section of the penis, demonstrating the relationship between the corporal bodies, penile fascia, vessels, and nerves. (From Devine CJ Jr, Angermeier KW. *Anatomy of the penis and male perineum*. AUA Update Series 1994;13:10–23.)

Figure 21-32. Electron microscopy of a myoendothelial junction (MEJ) in human corpus cavernosal tissue. The MEJ is extending from the endothelial cell (EC) through the internal elastic lamina (IEL) to communicate with the vascular smooth muscle cell (VSMC).

Arterial Supply

There is a superficial arterial system supplying the penis, which originates from the external pudendal arteries, and a deep arterial system that arises from each side from the internal pudendal arteries. The pudendal artery branches into a deep artery, supplying the corpora cavernosa, a dorsal artery, and the bulbourethral artery. Above the perineal membrane, the common penile artery travels in the Alcock canal, and it supplies the corpora cavernosa via three branches. The bulbourethral artery penetrates the perineal membrane where it enters the corpus spongiosum from above at its posterolateral border. This provides arterial supply to the corpus spongiosum, glans, and urethra. The cavernosal artery penetrates the corpus cavernosum in the penile hilum to nearly the center of the erectile tissue. It provides straight and helicine arteries that supply the cavernous sinuses. After it travels between the crus and the pubis, the dorsal artery of the penis supplies the dorsal surfaces of the corporeal bodies. The dorsal artery travels between the dorsal vein and the dorsal penile nerve, and they all attach to the underside of Buck fascia. The dorsal artery travels distally toward the glans and supplies cavernous branches and circumferential branches to the urethra and the corpus spongiosum (Devine and Angermeier, 1994). There can be a great deal of variability in penile arteries (Bare et al, 1994). A single cavernosal artery may supply both corpora cavernosa or it may be completely absent. In some cases, an accessory pudendal artery may supplement or completely take the place of branches of the common penile artery (Breza et al, 1989). The arterial supply to the penile skin is from the external pudendal branches of the femoral vessels. These vessels run longitudinally in the dartos fascia layer and provide a rich blood supply after entering the base of the penis (Fig. 21-33).

Venous Drainage

The superficial dorsal vein lies external to Buck fascia, whereas the deep dorsal vein is beneath Buck fascia and runs between dorsal arteries. A number of venous channels anastomose at the base of the glans to form the dorsal vein of the penis. **The dorsal vein travels between the corporeal bodies, in a groove, and drains into the preprostatic plexus.** In the distal two thirds of the penile shaft, the circumflex veins from the corpus spongiosum course around the corpora cavernosa to enter the deep dorsal vein perpendicularly. There are typically 3 to 10 circumflex veins. The cavernous sinuses form intermediary venules that empty into the subtunical capillary plexus. Emissary veins from these plexuses travel obliquely between the layers of the tunica and drain into the circumflex veins dorso-laterally. Emissary veins form two to five cavernous veins in the

Figure 21-33. Arterial supply of the penis.

proximal third of the penis, joining on the dorsomedial surface of the corpora cavernosa. These veins travel between the bulb and crura at the hilum of the penis. They receive branches from the bulb and the crura and empty into the internal pudendal veins.

Lymphatic Supply

Lymphatics from the skin of the penis drain to the superficial inguinal and subinguinal lymph nodes. **Penile shaft lymphatics converge on the dorsum and ramify to both sides of the groin to drain into inguinal lymph nodes.** Lymphatics from the glans run deep to Buck fascia dorsally to drain to the superficial and deep inguinal nodes bilaterally. Some studies have suggested direct lymphatic channels from the glans to pelvic nodes as well as studies proposing lymphatic drainage through sentinel nodes positioned medial to the superficial epigastric veins. These models have been challenged (Catalona, 1988).

Nerve Supply

Sensory innervation of the penis is through the dorsal nerves. These nerves richly supply the glans. The dorsal nerves travel alongside the dorsal arteries. Small branches of the perineal nerve supply the ventrum of the penis as distally as the glans (Uchio et al, 1999). The somatic nerve supply originates from spinal nerves S2, S3, and S4 via the pudendal nerve. The pudendal nerve passes through the Alcock canal and continues as the dorsal nerve of the penis. The cavernous nerves supply sympathetic and parasympathetic innervation from the pelvic plexus to the corporeal bodies after penetrating them to ramify in the erectile tissue (Fig. 21-34).

Cavernosogram

Cavernosograms were primarily used historically to assist in the diagnosis of venous leak erectile dysfunction. Radiopaque contrast is injected into the corporal body with plain film imaging. This is not a commonly used diagnostic test any longer, but it is occasionally used at the time of penile fracture repair (Fitzpatrick and Cooper, 1975; Mydlo et al, 1998) (Fig. 21-35).

KEY POINTS: PENIS

- The paired erectile bodies are known as the corpora cavernosa.
- The glans penis is an expansion of the corpus spongiosum.
- A permeable septum separates the corpora cavernosa for free communication between their vascular spaces.
- The superficial arterial system to the penis originates from the external pudendal arteries, and a deep arterial system arises from the internal pudendal arteries.
- The dorsal vein runs between the corporeal bodies and drains into the preprostatic plexus.
- Penile shaft lymphatics converge on the dorsum and ramify to both sides of the groin to drain into inguinal lymph nodes.
- Sensory innervation of the penis is through the dorsal nerves, and the somatic nerve supply originates from spinal nerves S2, S3, and S4 via the pudendal nerve.

SCROTUM

Gross Structure

The scrotal skin is hair bearing, pigmented, with abundant sebaceous and sweat glands, and has an absence of fat. It is variable

Figure 21-34. Dorsal penile arteries, veins, and nerves. (From Hinman F Jr. *Atlas of urosurgical anatomy*. Philadelphia: Saunders; 1993. p. 445.)

Figure 21-35. Angiogram of arteriocorporeal fistula in patient with nonischemic priapism showing filling of the right corpus cavernosum.

and may be folded with transverse rugae or it may appear loose and shiny. Its appearance depends on the tone of the underlying dartos smooth muscle. The median raphe runs longitudinally in the midline from the urethral meatus to the anus. Deep to the raphe, the scrotum is divided by a septum into two compartments, each containing a testis. The smooth muscle of the dartos fascia underlying the skin is continuous with Colles, Scarpa, and the dartos fascia of the penis. The spermatic fasciae are layers of the abdominal wall that extend to form parts of the scrotal wall. The external oblique extends to form the external spermatic fascia, which attaches to the borders of the external inguinal ring. The internal oblique extends to form the cremaster muscle and fascia, which attach to the inguinal ligament laterally, to the iliopsoas laterally, and to the pubic tubercle medially. The transversalis fascia continues to become the internal spermatic fascia in the scrotum. A peritoneal derivative known as the parietal and visceral tunica vaginalis surrounds the testis with a

mesothelium-lined pouch. The tunica vaginalis is continuous with the testis posterolaterally at its mesentery, where it is attached to the scrotal wall. The gubernaculum fixes the testis at its inferior pole (Fig. 21-36).

Arterial Supply

The external pudendal arteries supply the anterior wall of the scrotum. The arteries run parallel to the rugae and do not cross the median raphe. The posterior aspect of the scrotum has arterial supply from perineal branches. Arterial supply to the spermatic fascia is from the cremasteric, testicular, and deferential branches.

Venous Drainage

The external pudendal veins drain the anterior scrotal wall. The veins run parallel to the rugae and do not cross the median raphe.

Lymphatic Supply

Scrotal lymphatics do not cross the median raphe and drain into the superficial inguinal nodes on the ipsilateral side.

Nerve Supply

Branches of the ilioinguinal and genitofemoral nerves innervate the anterior scrotal wall. The nerves run parallel to the rugae and do not cross the median raphe. The posterior aspect of the scrotum receives innervation from scrotal branches of perineal nerves as well as from branches of the posterior femoral cutaneous nerve (S3).

KEY POINTS: SCROTUM

- The smooth muscle of the dartos fascia underlying the scrotal skin is continuous with Colles, Scarpa, and the dartos fascia of the penis.
- The scrotal wall arteries run parallel to the rugae and do not cross over the median raphe.
- Branches of the ilioinguinal and genitofemoral nerves innervate the anterior scrotal wall.

Hypothalamic-Pituitary-Gonadal Axis

Testis

Epididymis

Ductus (Vas) Deferens

Seminal Vesicle and Ejaculatory Ducts

Spermatozoa

Summary

The male reproductive axis of hormones and organs is an efficient, well-orchestrated, and precisely managed biologic system that has evolved over millions of years. It is responsible for reproductive tract formation and development, fertility potential at puberty, and the maintenance of adult maleness. This chapter explores our current understanding of this complex system by defining the anatomy and physiology of its components, including the hypothalamic-pituitary-gonadal (HPG) hormonal axis, spermatogenesis and androgen production within the testicle, and maturation and transport of sperm in the ductal system. In addition, new concepts in genetic infertility, stem cell science, and ejaculatory physiology are explained. Through such rigorous intellectual dissection, the true beauty and sophistication of the reproductive process is appreciated.

HYPOTHALAMIC-PITUITARY-GONADAL AXIS

The HPG axis plays a critical role during development and adulthood in four physiologic processes: (1) **phenotypic gender** development during embryogenesis, (2) **sexual maturation** at puberty, (3) testis endocrine function—**testosterone production**, and (4) testis exocrine function—**sperm production**.

Basic Endocrine Concepts

Two types of hormones mediate communication in the reproductive axis: peptide and steroid. **Peptide hormones are small, secretory proteins that act through cell surface receptors.** Hormone signals are transduced by one of several second-messenger pathways (Fig. 22-1). Ultimately, most peptide hormones induce phosphorylation of proteins that alter cell function. Examples of peptide hormones are luteinizing hormone (LH) and follicle-stimulating hormone (FSH). In contrast, **steroid hormones are derived from cholesterol. They are not stored in secretory granules; consequently, steroid secretion directly reflects rates of hormone production.** In plasma, these hormones are usually bound to carrier proteins, and because they are lipophilic, steroid hormones are cell membrane permeable. After binding to intracellular receptors, steroids are translocated to nuclear DNA recognition sites and regulate target gene transcription. Examples of reproductive axis steroid hormones are testosterone and estradiol.

Hormonal signaling within the HPG axis is hierarchically governed by a free-running pulse generator within the hypothalamus. The amplitude and frequency with which hormone secretions occur within the reproductive axis determine downstream organ responsiveness. Feedback control is the principal mechanism through which hormonal regulation occurs in the HPG axis (Fig. 22-2). With feedback control, a hormone can regulate the synthesis and action

of itself or of another hormone. **In the HPG axis, negative feedback activity is primarily responsible for minimizing perturbations and maintaining homeostasis.**

Components of the Reproductive Axis

Hypothalamus

As the integrative center of the HPG axis, the hypothalamus receives neuronal input from the amygdala, thalamus, pons, retina, olfactory cortex, and many other areas (see Fig. 22-2). The pulse generator for the cyclic secretion of pituitary hormones, **the hypothalamus is anatomically linked to the pituitary gland by both a portal vascular system and neuronal pathways.** By avoiding the systemic circulation, the portal vascular system allows direct delivery of hypothalamic hormones to the anterior pituitary.

The most important hypothalamic hormone for reproduction is **gonadotropin-releasing hormone (GnRH) or luteinizing hormone-releasing hormone (LHRH)**, a 10-amino acid peptide generated in the neuronal cell bodies in the preoptic and arcuate nuclei. **Currently, the only known function of GnRH is to stimulate the secretion of LH and FSH from the anterior pituitary.** GnRH has a plasma half-life of approximately 5 to 7 minutes and is almost entirely removed on the first pass through the pituitary either by receptor internalization or enzymatic degradation. GnRH secretion results from integrated input from the effects of stress, exercise, and diet from higher brain centers, gonadotropins secreted from the pituitary, and circulating gonadal hormones. Substances known to regulate GnRH secretion are listed in Table 22-1. In Kallman syndrome, characterized by congenital hypogonadotropic hypogonadism, the GnRH precursor neurons fail to migrate normally, with a subsequent absence of hypothalamic GnRH secretion (Bick et al, 1992; Dode et al, 2003). Affected individuals have delayed puberty or infertility owing to lack of testosterone production.

GnRH output exhibits several types of rhythmicity: seasonal, on a time scale of months and peaking in the spring; circadian, resulting in higher testosterone levels during the early morning hours; and pulsatile, with GnRH peaks occurring every 90 to 120 minutes on average. The importance of pulsatile GnRH secretions in normal HPG axis function is aptly demonstrated by the ability of exogenous GnRH agonists (e.g., leuprolide acetate) to stop testicular testosterone production by changing pituitary exposure to GnRH from a cyclic to a constant pattern.

Anterior Pituitary

Located within the bony sella turcica of the skull, the pituitary has two lobes: posterior and anterior. The posterior lobe, or

Figure 22-1. Two kinds of hormone classes mediate intercellular communication in the reproductive hormone axis: peptide and steroid. (Modified from Turek PJ. Male infertility. In: Tanagho EA, McAninch JC, editors. *Smith's urology*. 16th ed. Stamford [CT]: Appleton & Lange; 2008.)

Figure 22-2. Diagram of the hypothalamic-pituitary-testis hormonal axis. +, Positive feedback; –, negative feedback; FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone; PRL, prolactin; T, testosterone. (Modified from Turek PJ. Male infertility. In: Tanagho EA, McAninch JC, editors. *Smith's urology*. 16th ed. Stamford [CT]: Appleton & Lange; 2008.)

neurohypophysis, secretes two hormones, oxytocin and vasopressin, and is driven by neural stimuli. In contrast, the anterior pituitary, or adenohypophysis, is regulated by blood-borne factors and is the site of action of GnRH (see Fig. 22-2). GnRH stimulates the production and release of FSH and LH by a calcium flux-dependent mechanism. The sensitivity of pituitary gonadotrophs for GnRH varies with an individual's age and hormonal status. LH and FSH are the primary pituitary hormones that regulate testis function. They are glycoproteins composed of two polypeptide chain subunits, termed α and β , each coded by a separate gene. The α subunit of each hormone is identical and is similar to that of all other pituitary hormones; biologic and immunologic activities are conferred by the unique β subunit. Both subunits are required for endocrine activity. Sugars linked to these peptide subunits,

TABLE 22-1 Substances That Modulate Gonadotropin-Releasing Hormone (GnRH) Secretion

GnRH MODULATOR	TYPE OF FEEDBACK	EXAMPLES
Opioids	Negative	β -Endorphin
Catecholamines	Variable	Dopamine
Peptide hormones	Negative	FSH, LH
Sex steroids	Negative	Testosterone
Prostaglandins	Positive	PGE ₂
Insulin	Positive	Insulin
Kisspeptins	Positive	Kisspeptin (puberty)
Leptins	Positive	Leptin

FSH, follicle-stimulating hormone; LH, luteinizing hormone; PGE₂, prostaglandin E₂.

consisting of oligosaccharides with sialic acid residues, differ in content between FSH and LH and likely account for differences in their plasma clearance rates. Secretory pulses of LH vary in frequency from 8 to 16 pulses in 24 hours and vary in amplitude by onefold to threefold. These pulse patterns closely reflect GnRH release. Both androgens and estrogens regulate LH secretion through negative feedback. On average, FSH pulses occur approximately every 1.5 hours and vary in amplitude by 25%. The FSH response to GnRH is more difficult to assess than that of LH for two reasons: (1) FSH has a smaller amplitude response and a longer serum half-life, and (2) the gonadal proteins inhibin and activin may affect FSH secretion and are thought to account for the relative secretory independence of FSH from GnRH secretion.

FSH and LH are only known to act in the gonads. They activate adenylate cyclase, which leads to increases in intracellular cyclic adenosine monophosphate (cAMP). In the testis, LH stimulates steroidogenesis within Leydig cells by inducing the mitochondrial conversion of cholesterol to pregnenolone and testosterone. FSH binds to Sertoli cells and spermatogonial membranes within the testis and is the major stimulator of seminiferous tubule growth during development. FSH is essential for the initiation of spermatogenesis at puberty. In the adult, the major physiologic role of FSH is to stimulate quantitatively normal levels of spermatogenesis.

A third anterior pituitary hormone, prolactin, can also affect the HPG axis and fertility. Prolactin is a large, globular protein of 199 amino acids (23 kD) that is responsible for milk synthesis during pregnancy and lactation in women. No human mutations have been found in either the human prolactin gene or its receptor (Goffin et al, 2002). The normal role of prolactin in men is less clear, but it may increase the concentration of LH receptors on Leydig cells and sustain normal, high intratesticular testosterone levels. It may also potentiate the effects of androgens on the growth and secretions of the male accessory sex glands (Wennbo et al, 1997; Steger et al, 1998). Normal prolactin levels may be important to maintain libido. Although low prolactin levels are not necessarily pathologic, hyperprolactinemia abolishes gonadotropin pulsatility by interfering with episodic GnRH release. In addition, the anterior pituitary contains cells that secrete other glycoprotein hormones: adrenocorticotrophic hormone (ACTH), growth hormone (GH), and thyroid-stimulating hormone (TSH). These glycoprotein hormones can also have significant effects on male reproduction.

Testis

Normal male virility and fertility require the collaboration of the exocrine and endocrine testis (see Fig. 22-2). The interstitial compartment, composed mainly of Leydig cells, is responsible for steroidogenesis. The seminiferous tubules produce spermatozoa.

Normal testosterone production in men is approximately 5 g/day, and secretion occurs in a damped, irregular, pulsatile

manner (nyctohemeral). Testosterone is metabolized into two major active metabolites in target tissue: (1) the major androgen **dihydrotestosterone (DHT)** from the action of 5α -reductase, and (2) the estrogen **estradiol** through the action of aromatases. DHT is a much more potent androgen than is testosterone. In most peripheral tissues, testosterone reduction to DHT is required for androgen action, but in the testis and skeletal muscle, conversion to DHT is not essential for hormonal activity.

The primary site of FSH action is on Sertoli cells within seminiferous tubules. In response to FSH, Sertoli cells produce androgen-binding protein (ABP), transferrin, lactate, ceruloplasmin, clusterin, plasminogen activator, prostaglandins, and growth factors. Through these FSH-mediated factors, seminiferous tubule growth is stimulated during development, and sperm production is initiated during puberty. It is interesting to note that mice FSH knockout studies suggest that FSH is not essential for spermatogenesis, because affected mice can be fertile (Levallet et al, 1999). In humans, it is thought that FSH is required for normal spermatogenesis (Tapanainen et al, 1997).

The testis also produces the protein hormones **inhibin** and **activin** (Itman et al, 2006). Inhibin is a 32-kD protein made by Sertoli cells that inhibits FSH release from the pituitary. Within the testis, inhibin production is stimulated by FSH and acts by negative feedback at the pituitary or hypothalamus. Activin, a testis protein with close structural homology to transforming growth factor- β (TGF- β), exerts a stimulatory effect on FSH secretion. Activin receptors are found in a host of extragonadal tissues, suggesting that this hormone may have growth factor or regulatory roles in the body.

Negative feedback suppression of GnRH release by testosterone occurs through androgen receptors (ARs) in hypothalamic neurons and in the pituitary. In studies of genetic mutations, it is clear that both testosterone and estrogen participate in negative feedback (Shupnik and Schreihof, 1997). Steroid negative feedback results mainly from AR binding to testosterone, with a smaller contribution from estradiol binding. Testosterone feedback occurs mainly at the hypothalamus, whereas estrogen feedback is mainly in the pituitary (Santen, 1975). It also appears that although testosterone is the primary regulator of LH secretion, estradiol (along with inhibin from Sertoli cells) is the predominant regulator of FSH secretion (Hayes et al, 2001).

Development of the Hypothalamic-Pituitary-Gonadal Axis

Sex determination is genetically determined in humans. A critical gene for sex determination is **SRY** (sex-determining region Y gene) on the short arm of the Y chromosome. The SRY gene product is a protein with a high mobility group box (HMG) sequence, a highly conserved DNA-binding motif that kinks DNA. This DNA bending effect alters gene expression, leading to testis formation and subsequently to the male phenotype. However, the SRY gene does not act in isolation to determine human sex. **DAX1**, a nuclear hormone receptor gene, can alter SRY activity during development by suppressing genes downstream to SRY that would normally induce testis differentiation. A second gene, **WNT4**, largely confined to the adult ovary, may also serve as an "antitestis" gene. The discovery of these genes has significantly altered theories of sex determination. In the past, the female genotype was considered the "default," SRY-negative, developmental pathway. It is now clear that genes such as **WNT4** and **DAX1** can proactively induce female gonadal development, even in the presence of SRY (DiNapoli and Capel, 2008).

Once gonadal sex is determined, Leydig cells make **testosterone**, which induces development of the **internal genitalia** (Fig. 22-3). Leydig cells also synthesize **insulin-like growth factor-3** to promote **transabdominal testis migration** into the scrotum. DHT masculinizes the genital anlage to form the **external genitalia** (see Fig. 22-3). In addition, Sertoli cells within the developing testis synthesize **müllerian-inhibiting substance (MIS, or antimüllerian hormone [AMH])**, which prevents the müllerian duct from developing into uterus and fallopian tubes and keeps the early germ

Figure 22-3. Diagram of internal and external genitalia development. Testosterone is the main androgenic steroid responsible for the developing male internal genitalia, whereas dihydrotestosterone is the main androgen responsible for development of male external genitalia.

Figure 22-4. Early differentiation pathway of the male. MIS/MIF, müllerian inhibiting substance or factor. (Modified from Turek PJ. Male infertility. In: Tanagho EA, McAninch JC, editors. Smith's urology. 16th ed. Stamford [CT]: Appleton & Lange; 2008.)

cells quiescent in the testis (Fig. 22-4). In general, deficiencies in these developmental pathways result in either birth defects or intersex disorders.

The hormonal feedback relationships within the HPG axis become established during gestation. The expression of **kisspeptin** protein is in part responsible for activating GnRH neurons and triggering GnRH release. In addition, SF-1, an orphan nuclear receptor, is secreted by developing Sertoli cells and contributes to HPG axis development (Val et al, 2003). After the withdrawal of placental steroids at birth, there is a period of high gonadotropin secretion in the neonate. Subsequently, as axis sensitivity to gonadotropins increases, FSH and LH secretions fall to the low levels characteristic of childhood. Puberty begins with GnRH pulsing, leading gonadotropins to increase to adult levels and subsequently to increase sex hormones. The hypothalamic capacity to generate GnRH pulses arises at puberty, usually starting around the 12th year in males. Puberty begins at critical growth, weight, and nutritional rates for boys and girls and is likely initiated by

kisspeptin, melatonin, and leptin (Clement et al, 1998). The adipocyte hormone leptin is the body's regulatory signal governing the size of the fat stores, and there is increasing evidence that leptin modulates hypothalamic and pituitary activity (Caprio et al, 1999; Kiess et al, 1999; Quinton et al, 1999).

Aging and the Hypothalamic-Pituitary-Gonadal Axis

A progressive decline in testosterone and sperm production occurs with age, such that men in the seventh decade have mean plasma testosterone levels 35% lower than young men (Vermeulen et al, 1995). The consequence of this is a phenomenon that has been variously termed **male menopause**, **male climacteric**, **andropause**, or, more appropriately, **partial androgen deficiency in the aging male (PADAM)**. The changes to the seminiferous epithelium with age include decreases in seminiferous tubule volume and length. An age-related decrease in sperm production in older testes appears to stem from decreased germ cell proliferation rather than increased cellular degeneration. Correspondingly, FSH levels also increase with age, with mean values threefold higher in older than younger men. The cause of the age-related decline in HPG axis function is multifactorial. Testosterone production is reduced because of fewer Leydig cells and more testosterone-binding proteins. Diurnal variation of testosterone secretion is also lost in elderly men. With age, there is also evidence for a blunted HPG feedback response to low testosterone (despite generally high levels of gonadotropins) and to GnRH stimulation. Finally, normal pulsatile GnRH release is replaced by irregular pulses that are less effective in stimulating gonadotropin release (Mulligan et al, 1997). A combination of these effects is likely responsible for diminished HPG axis function with age.

KEY POINTS: HYPOTHALAMIC-PITUITARY-GONADAL AXIS

- Normal testosterone and sperm production depends on the pulsatile secretion of hypothalamic GnRH and LH and FSH from the anterior pituitary gland.
- Regulation of HPG axis hormones occurs primarily through negative feedback.
- The determination of maleness is derived from the SRY gene on the Y chromosome. However, developmental genes such as *WNT4* and *DAX1* are considered antitestis genes and can proactively induce female gonadal development.
- Changes to the HPG axis with paternal age include lower testosterone levels, blunted axis feedback, and irregular hormone pulsatility.

TESTIS

Gross Architecture

The testis is a white, ovoid organ that is normally 15 to 25 mL in volume (Prader, 1966) and has a length of 4.5 to 5.1 cm (Tishler, 1971; Winter and Faiman, 1972). The tunica albuginea has smooth muscle cells that course through predominantly collagenous tissue (Langford and Heller, 1973). Smooth muscle cells may impart contractile capability to the capsule (Rikmaru and Shirai, 1972), may affect blood flow into the testis (Schweitzer, 1929), and promote the flow of seminiferous tubule fluid from the testis (Davis and Horowitz, 1978).

The testis parenchyma is divided into compartments by septa. Each septum divides seminiferous tubules into lobes that each contain a centrifugal artery. Individual seminiferous tubules harbor developing germ cells. Interstitial tissue is composed of Leydig cells, mast cells, macrophages, nerves, and blood and lymph vessels. In humans, interstitial tissue comprises 20% to 30% of total testicular volume (Setchell and Brooks, 1988). The

relationship between seminiferous tubules and interstitial tissue anatomy is demonstrated in Figure 22-5. Seminiferous tubules are long, highly coiled, and looped. Both ends terminate in the rete testis. The combined length of the 600 to 1200 tubules in the human testis is estimated to be 250 meters (Lennox and Ahmad, 1970) (Fig. 22-6). The "hub" of the testis, also termed the rete testis, coalesces to form 6 to 12 ductuli efferentes that carry testicular fluid and spermatozoa into the caput epididymis (see Fig. 22-6).

The arterial supply to the testis and epididymis is derived from three sources: the internal spermatic artery, the deferential (vasal) artery, and the external spermatic (or cremasteric) artery (Harrison and Barclay, 1948). The internal spermatic artery arises from the abdominal aorta and is intimately associated with the pampiniform plexus of veins. The vascular arrangement within the pampiniform plexus, with the counterflowing artery and veins, facilitates the exchange of heat and small molecules. For example, testosterone passively diffuses from veins to the artery in a concentration-limited manner (Bayard et al, 1975). The counter-current heat exchange supplies arterial blood to the testis that is 2° C to 4° C lower than the rectal temperature in normal men (Agger, 1971). A loss of the temperature differential is associated with testicular dysfunction in men with varicocele (Goldstein and Eid, 1989) and cryptorchidism (Marshall and Edler, 1982). As the spermatic cord is commonly dissected during varicocele repair, it is surgically relevant to know that a single artery is observed in 50% of spermatic cords, with two arteries in 30% and three arteries in 20% of cases (Beck et al, 1992).

Inferior to the scrotal pampiniform plexus and near the mediastinal testis, the spermatic artery is highly coiled and branches before entering the testis. Extensive interconnections, especially between the internal spermatic and deferential arteries, allow maintenance of testis viability even after division of the internal spermatic artery (Fig. 22-7). From angiographic studies, a single artery enters the testis in 56% of cases; two branches enter in 31% of cases, and three

Figure 22-6. Drawing of the human testis showing the seminiferous tubules (250 meters in length), epididymis (3 to 4 meters in length), and vas deferens. (Based on Hirsh AV. The anatomical preparations of the human testis and epididymis in the Glasgow Hunterian Collection. *Hum Reprod Update* 1995;1:515–21.)

or more branches in 13% of testes (Kormano and Suoranta, 1971). In men with a single testicular artery, its interruption can result in testicular atrophy (Silber, 1979). The testicular arteries penetrate the tunica albuginea and then travel inferiorly along the posterior surface of the testis within the parenchyma. Branching arteries pass anteriorly over the testicular parenchyma. Major testicular artery branches also travel over the inferior pole of the testis, pass anteriorly, and branch out over the surface of the testis. The location of these vessels is clinically important, because they may be injured during orchiopexy or testis biopsy procedures (Jarow, 1991; Schlegel and Su, 1997). The midsection of the testis has relatively fewer vessels compared with superior or inferior areas. Individual arteries to the seminiferous tubules, termed *centrifugal arteries*, travel within the septa, which contain tubules. Centrifugal artery branches give rise to arterioles that supply individual intertubular and peritubular capillaries (Muller, 1957). The intertubular capillaries are located within the columns of interstitial tissue, whereas the ladder-like capillaries running near the seminiferous tubule are called *peritubular capillaries*. Through this vascular complex, the human testis is provided with 9 mL of blood per 100 g of tissue per minute (Pettersson et al, 1973).

Veins within the testis are unusual in that they do not run with the corresponding intratesticular arteries. Small parenchymal veins empty either into the veins on the testis surface or into a group of veins near the mediastinum testis that travels along the rete testis (Setchell and Brooks, 1988). These two sets of veins join together with deferential veins to form the pampiniform plexus as they ascend into the scrotum. Pampiniform plexus veins are thin walled, which likely contributes to the passive diffusion of testosterone and heat with the closely associated spermatic artery.

The testis has no known somatic innervation. It receives autonomic innervation primarily from the intermesenteric nerves and renal plexus (Mitchell, 1935). These nerves run along the testicular artery into the testis. It appears that testicular adrenergic innervation

Figure 22-7. Schematic illustration of interconnections between internal spermatic, external spermatic (cremasteric), and deferential vessels in the peritesticular region and spermatic cord.

is restricted primarily to small blood vessels that supply Leydig cell clusters that may regulate Leydig cell steroidogenesis (Baumgarten et al, 1968; Turnbull and Rivier, 1997). It is thought that vascular tone in the testis may involve regulation at several levels (Linzell and Setchell, 1969), including autoregulation of capsular arteries (Davis et al, 1990), regional variation based on local metabolic need and governed by peptides such as atrial natriuretic peptide (Collin et al, 1997), and assisted transport of molecules such as LH across the vascular endothelium (Milgrom et al, 1997). Indeed, these observations suggest a highly specialized function for the microvasculature of the testis (see review by Desjardins [1989]).

Prominent lymphatics can be observed within the spermatic cord (Hundeiker, 1971). Obstruction of these ducts results in dilation of the testis interstitium but not the seminiferous tubules, suggesting that the interstitial space is drained by lymphatics, but the seminiferous tubules are not. Lymphatic obstruction can also result in hydrocele formation, a known complication of varicocelelectomy and herniorrhaphy procedures. The sperm-containing intratubular fluid that bathes Sertoli cells flows from the seminiferous tubules into the rete testis and subsequently into the caput epididymis. This fluid, isosmotic with plasma, is thought to be mainly of seminiferous tubule origin (Setchell and Brooks, 1988). Reabsorption of this fluid within the rete testis and efferent ductules is regulated by estrogens (Lee et al, 2000). Tubular fluid composition is markedly different from blood plasma or

lymphatics, suggesting that substances are not freely diffusible into and out of the tubules (Setchell and Waites, 1975). This has led to the concept of a “blood-testis barrier” to be discussed later.

Testis Cytoarchitecture

Interstitial

Leydig Cells. The testis interstitium contains blood vessels, lymphatics, fibroblasts, macrophages, mast cells, and Leydig cells (Fig. 22-8). Leydig cells are responsible for the bulk of testicular steroid production. Leydig cells differentiate from mesenchymal

precursor cells by the 7th week of gestation. The activation of Leydig cell steroidogenesis correlates with the onset of androgen-dependent differentiation of the male reproductive system. Although Leydig cells express steroidogenic enzymes before becoming responsive to LH (El-Gehani et al, 1998; Majdic et al, 1998), they also differentiate from precursors under the influence of LH and placental-derived human chorionic gonadotropin (hCG) and from the effect of local paracrine factors such as insulin-like growth factor-1 (IGF-1) (Huhtaniemi and Pelliniemi, 1992; Teerds and Dorrington, 1993; Le Roy et al, 1999). At 2 to 3 months after birth, a second wave of Leydig cell differentiation occurs in response to pituitary gonadotropin production, briefly elevating

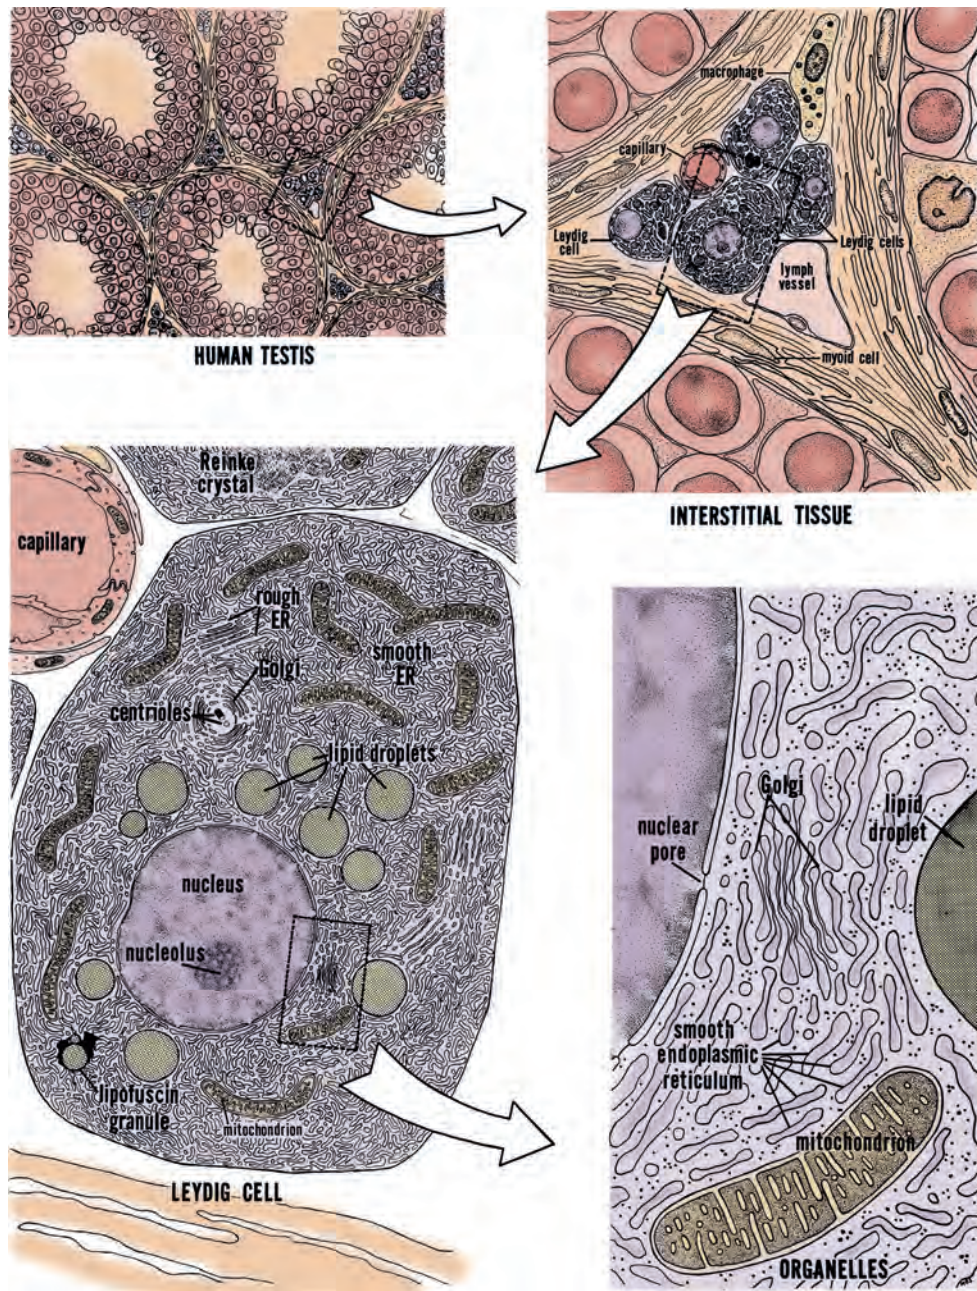

Figure 22-8. Fine structure of human Leydig cells. Leydig cells occur in clusters in the interstitium between seminiferous tubules (upper left). Interstitial tissue (upper right) contains macrophages and fibroblasts and capillaries and lymph vessels. The most abundant organelle within the Leydig cell cytoplasm is the smooth endoplasmic reticulum (lower left). Organelles seen in greater detail (lower right). (From Christensen AK. Leydig cells. In: Greep RO, Astwood WB, editors. Handbook of physiology. Baltimore: Williams & Wilkins; 1975. Copyright 1975, American Physiological Society, Bethesda, MD.)

testosterone levels. Androgen produced during the early male neonate's life is thought to hormonally imprint the hypothalamus, liver, and prostate such that they respond appropriately to androgen stimulation later in life. After reactivation of the HPG axis at puberty, stereologic analysis has revealed that a single testis from a young adult contains approximately 700 million Leydig cells (Kaler and Neaves, 1978).

Testosterone. Testosterone, synthesized from cholesterol, is the principal steroid produced by the testis (Lipsett, 1974). Numerous C18, C19, and C21 steroids are also produced (Lipsett, 1974; Ewing and Brown, 1977). Cholesterol must be transported into Leydig cell mitochondria, where the cholesterol side-chain cleavage enzyme converts it to pregnenolone. The three main sources of cholesterol in the Leydig cell are (1) external, from blood-borne lipoprotein and internalization of cholesterol-lipoprotein receptor complexes, (2) de novo synthesis from acetate, and (3) stored cholesterol esters in lipid droplets. Maintenance of cholesterol stores is part of normal Leydig cell function; LH stimulation evokes cholesterol mobilization through cholesterol esterase activity. Pregnenolone is transported out of the mitochondrial membrane into the smooth endoplasmic reticulum, where it is converted into testosterone. Testosterone diffuses across the cell membrane and is trapped within the extracellular fluid and blood plasma by steroid-binding proteins.

Cholesterol transport to the inner membrane of the mitochondrion is regulated by two transport proteins: steroid acute regulatory protein (StAR) and peripheral benzodiazepine receptor (PBR). LH binding elicits StAR synthesis in the Leydig cell, which then threads through the outer mitochondrial membrane to facilitate cholesterol transport (Stocco, 2000). PBR forms a channel

for cholesterol in the mitochondrial membrane (Culty et al, 1999), but it is not clear whether PBR functionally interacts with StAR (West et al, 2001).

The four major enzymes participating in testosterone biosynthesis from pregnenolone are cholesterol side-chain cleavage enzyme, 3β -hydroxysteroid dehydrogenase, cytochrome P450 17α -hydroxylase/C17-20-lyase, and 17β -hydroxysteroid dehydrogenase. The enzymology, chromosomal locations, and molecular genetics of these enzymes are well described (Payne and Hales, 2004). Mutations in the genes encoding these enzymes have been described and the resulting disorders of androgen biosynthesis are a relatively rare cause of sexual ambiguity in chromosomally normal males (Miller, 2002).

Control of Testosterone Synthesis. The control of Leydig cell steroidogenesis is complex and involves both pituitary and nonpituitary factors (Payne and Youngblood, 1995). The most important regulator of testosterone production is LH. After binding LH, through the second messenger cAMP, Leydig cells initiate transport of cholesterol into mitochondria. Pituitary peptides other than LH (e.g., FSH and prolactin) modify the response to LH (Ewing, 1983). Other, nonpituitary factors capable of modifying steroid production by Leydig cells include GnRH (Sharpe, 1984); inhibin and activin (Bardin et al, 1989); epidermal growth factor (EGF), IGF-1, and TGF- β (Ascoli and Segaloff, 1989; Saez et al, 1991); prostaglandins (Eik-Nes, 1975); and adrenergic stimulation (Eik-Nes, 1975). Moreover, direct inhibition of Leydig cell steroidogenesis may also occur through estrogens and androgens (Ewing, 1983; Darney et al, 1996).

Testosterone Cycles. Testosterone blood levels change dramatically during human fetal, neonatal, and adult life. Figure 22-9

Figure 22-9. Peripheral blood testosterone levels in the human male during the life cycle. The fetal testosterone peak occurs at 12 to 18 weeks of gestation (*lower left corner; gestational age not shown*). The neonatal peak occurs at approximately 2 months of age. Testosterone declines to low levels during the prepubertal period. The pubertal increase in testosterone occurs at 12 to 17 years of age. Testosterone concentration in the adult reaches its maximum during the second or third decade of life and then declines slowly. Testosterone declines dramatically during senescence. *Inset A* shows the annual rhythm in testosterone concentration in the human male. The peak and nadir occur in the fall and spring, respectively. *Inset B* shows the daily rhythm in testosterone concentration. The peak and nadir occur in the morning and evening, respectively. *Inset C* shows the frequent and irregular fluctuations in testosterone concentration. (From Ewing LL, Davis JC, Zirkin BR. Regulation of testicular function: a spatial and temporal view. In: Greep RO, editor. International review of physiology. Baltimore: University Park Press; 1980. p. 41.)

shows that a testosterone peak occurs in the human fetus at 12 to 18 weeks of gestation. Another testosterone peak occurs at approximately 2 months of age. A third testosterone peak occurs during the second or third decade of life. After this, there is a plateau, and then a slow decline with age. Superimposed on this, there are annual and daily rhythms of testosterone production (see Fig. 22-9, insets A and B) and irregular daily fluctuations in testosterone (see Fig. 22-9, inset C). These temporal changes in testosterone production during human life reflect a complex interaction between the pituitary gland and testis. **The testosterone peaks correspond temporally to four developmental events: (1) the differentiation and development of the fetal reproductive tract, (2) the neonatal organization or "imprinting" of androgen-dependent target tissues, (3) the masculinization of the male at puberty, and (4) the maintenance of growth and function of androgen-dependent organs in the adult.** This topic has been reviewed thoroughly by Swerdloff and Heber (1981).

Seminiferous Tubules

The seminiferous tubules consist of germ cells and supporting cells and are a unique environment for gamete production. Support cells include Sertoli cells and fibrocyte and myoid cells of the basement membrane. The germ cells include a slowly dividing stem cell population, more rapidly proliferating spermatogonia and spermatocytes, and metamorphosing spermatids.

Sertoli Cells. The seminiferous tubules are lined with Sertoli cells that rest on the tubular basement membrane and extend cytoplasmic ramifications into its lumen (Fig. 22-10). The ultrastructural features of Sertoli cells are well described (Bardin et al, 1994). They have irregularly shaped nuclei, prominent nucleoli, and a low mitotic index and exhibit unique **tight junctional complexes** between adjacent Sertoli cells. **These tight junctions are the strongest intercellular barriers in the body. They divide the seminiferous tubule space into basal (basement membrane) and adluminal (lumen) compartments** (see Fig. 22-10). This anatomic arrangement forms the basis for the **blood-testis barrier** and allows spermatogenesis to occur in an immunologically privileged site. Sertoli cells serve as nurse cells for spermatogenesis, nourishing developing germ cells within and between Sertoli cell cytoplasmic projections. The undifferentiated spermatogonia are near the basement membrane of the tubule, whereas the more advanced spermatocytes and spermatids are near the luminal surface. Thus the Sertoli cell is a polarized epithelium in which the base approximates the plasma environment, and its apex harbors an environment unique to the seminiferous tubule (Ewing et al, 1980).

Sertoli cells nurture germ cell development by (1) providing a specialized adluminal microenvironment, (2) supporting germ cells through gap junctions between Sertoli and germ cells, and (3) allowing migration of developing germ cells within the tubule (see Fig. 22-10). The tight junctions between Sertoli cells are constantly remodeled to allow "opening" and "closing" necessary for germ cell interaction and migration (Mruk and Cheng, 2004). Ligand-receptor complexes, such as c-kit and kit ligand, are likely involved in mediating communication between germ and Sertoli cells. Sertoli cells also participate in germ cell phagocytosis and produce and secrete fluid and important effector molecules. ABP is one of earliest described Sertoli cell secretory products (Hansson and Djoseland, 1972). ABP is an intracellular carrier of androgen within the Sertoli cell. **By binding testosterone, ABP maintains high levels of androgen (50-fold higher than serum) within the seminiferous tubules.** Testosterone also plays an important role in the regulation of Sertoli cell function, including ABP production (Griswold et al, 1988). Inhibin is Sertoli cell derived and plays an important regulatory role in the negative feedback loop of FSH secretion. Inhibin B is emerging as an important endocrine marker of Sertoli cell function in the male infertility evaluation.

As keepers of the immunologic sanctuary in the testis, Sertoli cells maintain a germ cell microenvironment entirely distinct from that of plasma. As such, Sertoli cells secrete numerous other products including extracellular matrix components (lamin, collagen

type IV, and collagen type I) and proteins such as ceruloplasmin, transferrin, glycoprotein 2, plasminogen activator, somatomedin-like substances, T proteins, H-Y antigen, clusterin, cyclic proteins, growth factors, and somatomedin (Mruk and Cheng, 2004). Steroids, such as DHT, testosterone, androstenediols, 17 β -estradiol, and numerous other C21 steroids are also produced by Sertoli cells (Ewing et al, 1980; Mather et al, 1983). Although the function of many Sertoli cell and peritubular-derived substances is unclear, further research should enlighten our understanding of how Sertoli cells orchestrate and support spermatogenesis.

Germ Cells. Within the human seminiferous tubule, germ cells give rise to approximately 123×10^6 (range, 21 to 374×10^6) spermatozoa daily (Amann and Howards, 1980). This equates to the production of about 1200 sperm per heartbeat. Within the seminiferous tubule, germ cells are arranged in a highly ordered sequence from the basement membrane to the lumen. **Morphologic analysis of the various germ cells reveals at least 13 recognizable germ cell types in the human testis** (Clermont, 1963; Heller and Clermont, 1964) (Fig. 22-11). Each cell type is thought to represent a different step in the spermatogenic process. Proceeding from the least to the most differentiated, based on morphologic appearance, they have been named **dark type A spermatogonia (Ad); pale type A spermatogonia (Ap); type B spermatogonia (B); preleptotene (R), leptotene (L), zygotene (Z), and pachytene (P) primary spermatocytes; secondary spermatocytes (II); and Sa, Sb, Sc, Sd₁, and Sd₂ spermatids.** The tight junctions maintain spermatogonia and early spermatocytes within the basal compartment and all subsequent germ cells in the adluminal compartment.

Peritubular Structure

The human seminiferous tubule is surrounded by several layers of peritubular tissue (Hermo et al, 1977) (Fig. 22-12). The outer adventitial layer consists of fibrocytes. In the middle layer are myoid cells interspersed with connective tissue lamellae. The inner layer consists of a collagen matrix. In humans the peritubular myoid cells are thought to have contractile function (Toyama, 1977). Myoid cells actively secrete extracellular matrix components fibronectin and collagen type I, and produce the inner collagenous layer (Tung et al, 1984). Myoid cells may also affect Sertoli cell function and are known to associate with Sertoli cells in a precise mesenchymal-epithelial interaction. Skinner and coworkers (1988) isolated a paracrine factor produced by myoid cells, P-Mod-S (peritubular modifies Sertoli), that profoundly affects Sertoli cell synthetic and differentiation functions in vitro. Human peritubular cells have also been shown to secrete testosterone and may influence Sertoli cell activity (Cigorrage et al, 1994).

Blood-Testis Barrier

Dyes and other substances, when injected into the bloodstream of animals, will rapidly appear throughout all body tissues but fail to penetrate regions of the brain and testis. This led to the concept of the existence of a blood-testis barrier. **More appropriately termed the "blood-seminiferous tubule barrier," it has two components: an anatomic or mechanical element and functional elements.** The mechanical barrier is created, in part, by muscle-like myoid cells that surround seminiferous tubules (Dym and Fawcett, 1970; Fawcett et al, 1970). Regulation of molecular traffic also occurs at the level of capillary endothelial cells. However, the most important component of this barrier is the synaptic tight junctions between Sertoli cells that preclude the passage of large molecules and lymphocytes. These anatomic elements of the barrier are necessary but not sufficient for maintaining the immunologic "sanctuary" status within the tubule, because they are not observed in other protected areas of the reproductive tract (Tung et al, 1971; Brown et al, 1972).

Thus, although the mechanical barrier contributes to the isolation of the testis, other "functional" components must also exist to suppress the normal immune response. Several mechanisms likely work in concert to protect sperm from destruction. First, lymphocytes are excluded from anatomically vulnerable regions in the

Figure 22-10. Representation of the tree-shaped Sertoli cell with a thickened central portion, or “trunk,” and more delicate processes, or “limbs.” Note the basal, intermediate, and adluminal compartments of the seminiferous epithelium. **A**, Spermatogonia and early spermatocytes share positions on the basal lamina and are enveloped by adjacent Sertoli cells that join to form tight junctional complexes (site of blood-testis barrier). **B**, Sertoli cells form junctional complexes both above and below leptotene-zygotene spermatocytes as they translocate from the basal to adluminal compartments. **C**, The spermatocytes enter the adluminal compartment when Sertoli tight junctions dissociate. **D**, The elongating spermatid is situated within a narrow recess of the Sertoli cell trunk. **E**, As the spermatid elongates further, the cell becomes lodged within the body of the Sertoli cell. The advanced spermatid moves toward the lumen of the epithelium in preparation for spermiation. Only the sperm head remains in intimate contact with the Sertoli cell. Specialized cell-to-cell contacts: *asterisks*, desmosome-gap junction complex; *arrowheads*, ectoplasmic specializations; *isolated arrows*, tubulobulbar complexes. (From Russell L. Sertoli-germ cell interactions: a review. *Gamete Res* 1980;3:179.)

Figure 22-11. The steps of spermatogenesis in man. Ad, dark type A spermatogonium; Ap, pale type A spermatogonium; B, type B spermatogonium; II, secondary spermatocyte; L, leptotene spermatocyte; P, pachytene spermatocyte; R, resting or preleptotene primary spermatocyte; Rb, residual body; Sa(a), Sb₁(b₁), Sb₂(b₂), Sc (c), Sd₁(d₁), Sd₂(d₂), spermatids; Z, zygotene spermatocyte. The table shows cells that make up the six stages of the “cycle” of the seminiferous epithelium (I to VI): D₁, diakinesis; I_D and II_D, first and second maturation divisions of spermatocytes. (Modified from Clermont Y. Renewal of spermatogonia in man. *Am J Anat* 1966;118:509.)

germinal epithelium (Mahi-Brown et al, 1988). Second, these vulnerable regions harbor mainly T-suppressor cells (el-Demiry et al, 1985; Anderson and Hill, 1988). Owing to deficiencies in antigen–human leukocyte antigen association, there may be a lack of sperm antigen presentation to lymphocytes, impairing the immune response (Jenkins et al, 1987; Anderson and Hill, 1988). There is also evidence to suggest that immunologic tolerance plays a role in the functional blood–testis barrier. The leading theory proposes that within the anatomically weaker areas (rete testis, efferent tubule, epididymis) of the barrier, there is a small, continuous leak of sperm antigens (Tung, 1980). This leak generates T-suppressor cells and immune tolerance, similar to desensitization protocols for common environmental allergens. However, with larger antigenic challenges, a true immune response results (Turek, 1997). Cytokines may contribute to immune tolerance, including interferon- γ , soluble Fc receptor, and TGF- β (Perussia et al, 1987; Ben-Rafael and Orvieto, 1992; Turek, 1997). In addition, androgens have mild immunosuppressive activity and may regulate immunity (Diemer et al, 2003).

Why does the blood–testis barrier exist? Since it develops at spermatogenesis during puberty (Korman, 1967), it is likely important for meiosis. In addition, it may immunologically isolate developing male gametes that are not recognized as self by the adult male

Figure 22-12. Low-power electron micrograph of human peritubular testis tissue. Peritubular tissue lies between the basement membrane (bm) of the seminiferous epithelium (SE) and the interstitial tissue (IS). Peritubular tissue has three zones: the inner lamella (IL); the myoid layer (M), containing myoid cells (MY) with abundant microfilaments (Mf); and an adventitial layer containing fibroblasts (F). (From Hermo L, Lalli M, Clermont Y. Arrangement of connective tissue elements in the walls of seminiferous tubules of man and monkey. *Am J Anat* 1977;148:433–46.)

immune system. In this sense, the value of a blood–testis barrier is fully realized after puberty, because foreign “antigens” on postmeiotic germ cells exist only after spermatogenesis. A testicular insult such as biopsy, torsion, or trauma will not induce anti-sperm antibodies if it occurs before puberty. After puberty, however, immunologic infertility is a known risk (Turek, 1997). Clinically, the blood–testis barrier may also limit chemotherapy access to cancer cells sequestered behind it and result in isolated cancer recurrence within the testis.

Spermatogenesis

Spermatogenesis is a remarkably complex and specialized process of DNA reduction and germ cell metamorphosis. Older studies have estimated that the entire process in humans requires approximately 64 days (Clermont, 1972). However, an *in vivo* kinetic study in healthy men revealed that the total time to produce an ejaculated sperm ranges from 42 to 76 days, suggesting that the duration of spermatogenesis can vary widely among individuals (Misell et al, 2006) (Fig. 22-13). Spermatogenesis involves (1) a proliferative phase as spermatogonia divide to replace their number (self-renewal) or differentiate into daughter cells that become mature gametes; (2) a meiotic phase when germ cells undergo a reduction division, resulting in haploid (half the normal DNA complement) spermatids; and (3) a spermiogenesis phase in which spermatids undergo a profound metamorphosis to become mature spermatozoa. (For excellent reviews, see Steinberger [1976] and de Kretser and Kerr [1988].)

A cycle of spermatogenesis involves the division of primitive spermatogonial stem cells into subsequent germ cells. Several cycles of spermatogenesis coexist within the germinal epithelium at any one time, and they are described morphologically as stages. If spermatogenesis is viewed from a single fixed point within a seminiferous tubule, six recognizable cellular associations or stages are predictably observed in humans (Heller and Clermont, 1964) (see Fig. 22-11). In addition, there is also a specific organization of spermatogenic cycles within the tubular space, termed *spermatogenic waves*. The best evidence suggests that human spermatogenesis exists in a spiral or helical cellular arrangement that ensures sperm production is a continuous and not a pulsatile process (Schulze, 1989) (Fig. 22-14).

Figure 22-13. Time to make and ejaculate human sperm. Combined spermatocyte labeling curves for 11 individuals with normal semen quality who ingested 50 mL of $^2\text{H}_2\text{O}$ twice daily for 3 weeks. New ejaculated sperm was found as early as 42 days after ingestion of label, and there was considerable interindividual variation in the time to make and ejaculate sperm. (From Misell LM, Holochwost D, Boban D, et al. A stable isotope/mass spectrometric method for measuring the kinetics of human spermatogenesis in vivo. *J Urol* 2006;175:242–6.)

Figure 22-14. Helical configuration of seminiferous tubule epithelial cycles in man, forming overlapping waves of spermatogenesis that keep sperm production constant. (From Schulze W, Rehder U. Organization and morphogenesis of the human seminiferous epithelium. *Cell Tissue Res* 1984;237:395–407.)

Testis Stem Cell Migration, Renewal, and Proliferation

Testis Stem Cell Migration. During early prenatal development, primordial germ cells migrate to the gonadal ridge and associate with Sertoli cells to form primitive testicular cords (Witschi, 1948). These primitive germline stem cells are termed **gonocytes** after the gonad differentiates into a testis by forming seminiferous cords.

They are called **spermatogonia** after migration to the periphery of the tubule (Gondos and Hobel, 1971). It is interesting to note that these early migrating germ cells have properties very similar to embryonic stem cells and are likely the source of adult germ cell tumors (Ezeh et al, 2005).

Testis Stem Cell Renewal. Spermatogonia within the testis stem cell niche are replenished in a process termed *stem cell renewal*. The growth factor receptor kit ligand/c-kit receptor system and the niche factor glial cell line–derived neurotrophic factor (GDNF) appear to be involved in this process (Oatley and Brinster, 2008). In fact, the c-kit receptor is a marker of spermatogonial stem cells in rats (Dym, 1994), and spermatogenesis in the rat is a c-kit–dependent process, whereas spermatogonial stem cell renewal may be c-kit independent (Yoshinaga et al, 1991). Recent studies have also shown that human spermatogonial stem cells can be reprogrammed in vitro to become embryonic-like stem cells (Conrad et al, 2008; Kossack et al, 2009) (Fig. 22-15). Obtained from adult testis biopsy specimens, the embryonic-like cells express distinct markers of pluripotency (OCT-4, SOX-2, STELLAR, GDF-3), can form all three germ layers, maintain a normal karyotype, form teratomas, and express appropriate levels of epigenetic markers and telomerase (Kossack et al, 2009). This finding suggests that in the future the testis may be a source of patient-specific stem cells for cell-based therapy.

Testis Stem Cell Proliferation. In the human, pale type A (Ap) spermatogonia in the basal, stem cell niche of the seminiferous tubule divide at 16-day intervals (Clermont, 1972) to form B spermatogonia. B spermatogonia are committed to become spermatocytes, but the cytoplasm between spermatogonial daughter cells remains conjoined after mitosis, forming cytoplasmic bridges between adjacent cells. These cytoplasmic bridges are observed between germ cells of all classes throughout spermatogenesis (Ewing et al, 1980). These bridges could be important for synchronized cellular proliferation and differentiation and for regulation of gene expression.

Meiosis

Somatic cells replicate by mitosis, in which genetically identical daughter cells are formed. **Germ cells replicate by meiosis, in which the genetic material is halved to allow reproduction.** Meiosis generates genetic diversity, providing a richer source of material on which natural selection can act. Cell replication by mitosis is a precise, well-orchestrated sequence of events involving duplication of the genetic material (chromosomes), breakdown of the nuclear envelope, and equal division of the chromosomes and cytoplasm into daughter cells. **The essential difference between mitotic and meiotic replication is that a single DNA duplication step is followed by only one cell division in mitosis, but two cell divisions in meiosis (four daughter cells).** Consequently, daughter cells contain only half of the chromosome content of parent cells. Thus a diploid ($2n$) parent cell becomes a haploid (n) gamete. Other major differences between mitosis and meiosis are outlined in Table 22-2. Research has shown that small RNA molecules (small RNAs), including small interfering RNAs (siRNAs), microRNAs (miRNAs), and piwi-interacting RNAs (piRNAs), are important regulators of gene germ cell expression at the post-transcriptional or translation level (Tolia and Joshua-Tor, 2007; He et al, 2009).

Spermatogenesis begins with type B spermatogonia dividing mitotically to form primary spermatocytes within the adluminal compartment. Mature spermatocytes are the first germ cells to undergo meiosis (Kerr and de Kretser, 1981). In this process, a meiotic division is followed by a typical mitotic reduction division, resulting in daughter cells with a haploid chromosome complement. In addition, as a consequence of chromosomal recombination, each daughter cell contains different genetic information. The resultant cell is the Sa spermatid (see Fig. 22-11).

Chromosomal recombination, the defining feature of mammalian meiosis, ensures that haploid gametes differ genetically from their adult precursors and is the real engine of genetic diversity and evolution. During meiotic prophase, formation of a synaptonemal complex with pairing of homologous (maternal and

Figure 22-15. Microphotograph of four different colonies of adult testis spermatogonial-derived stem cells. Cell clusters are the result of reprogramming of adult spermatogonia in culture conditions used for human embryonic stem cells (HESCs). They exhibit the typical cobblestone appearance of HESCs and are functionally multipotent.

paternal) chromosomes occurs, along with physical interaction and exchange of DNA through reciprocal sites of crossing over (**chiasmata**) between homologs. Recent research has shown that defects in the fidelity of recombination within human male germ cells can cause azoospermia and male infertility (Walsh et al, 2009). In one study, 10% of nonobstructive azoospermic men had significant defects in recombination compared with men with normal spermatogenesis (Gonsalves et al, 2004). In addition, among men with maturation arrest pattern on testis biopsy, faulty recombination was observed in about half of cases, providing evidence that faulty recombination is linked to poor sperm production (Gonsalves et al, 2004). Variations in recombination also have implications for sperm aneuploidy, because alterations in crossover position are risk factors for chromosomal nondisjunction. Indeed, evidence suggests that the correlation of faulty recombination and sperm aneuploidy in azoospermic men is strong enough to explain the higher rate of chromosomal abnormalities in offspring conceived with in vitro fertilization (IVF) and intracytoplasmic sperm injection (ICSI) (Sun et al, 2008).

Spermiogenesis

During spermiogenesis, round 4a spermatids mature into spermatozoa (see Fig. 22-11). During this maturation sequence, cell division does not occur, but there are extensive changes to the spermatid

TABLE 22-2 Essential Differences: Mitosis and Meiosis

MITOSIS	MEIOSIS
Occurs in somatic cells	Occurs in sexual cells
One cell division, two daughter cells	Two cell divisions, four daughter cells
Chromosome number maintained	Chromosome number halved
No pairing, chromosome homologs	Synapse of homologs, prophase I
No crossovers	More than one crossover per homolog pair
Centromeres divide, anaphase	Centromeres divide, anaphase II
Identical daughter genotype	Genetic variation in daughter cells

nucleus and cytoplasm. These include the loss of cytoplasm, migration of cytoplasmic organelles, formation of the acrosome from the Golgi apparatus, formation of the flagellum from the centriole, nuclear compaction to about 10% of former size, and reorganization of mitochondria around the sperm midpiece

(Kerr and de Kretser, 1981). The nucleus of the round spermatid changes from spheric to asymmetrical as chromatin condenses. Many cellular elements contribute to the reshaping process, including chromosome structure, associated chromosomal proteins, the perinuclear cytoskeletal theca layer, the manchette of nuclear microtubules, subacrosomal actin, and Sertoli cell interactions. With completion of spermatid elongation, the Sertoli cell cytoplasm retracts around the developing sperm, stripping it of all unnecessary cytoplasm and extruding it into the tubule lumen. The mature sperm has remarkably little cytoplasm and is produced in massive quantities—up to 300 per gram of testis per second.

Sertoli Cell–Germ Cell Interaction

A complex network of cell-cell interactions exists within the testis between Leydig cells and Sertoli cells, between Leydig cells and peritubular cells, between Sertoli and peritubular cells, and between Sertoli cells and germ cells. Several Sertoli cell–germ cell associations in mammalian testes are illustrated in Figure 22-10 (Russell and Clermont, 1976; Romrell and Ross, 1979; Skinner, 1995). In addition, there are factors that can reversibly disrupt the blood-testis barrier, including TGF- β 3 and tumor necrosis factor- α (TNF- α). These substances act by reducing the levels of occludin and zonula occludens-1 (ZO-1) in the barrier through a p38 mitogen-activated protein (MAP) kinase signaling pathway (Xia et al, 2009). This represents only a piece of the remarkably complex and highly interactive process that characterizes spermatogenesis.

Genetics

Genetic causes of abnormal spermatogenesis have been identified as point mutations in single genes inherited in mendelian fashion (e.g., cystic fibrosis), and as chromosomal disorders in which segments of (or entire) chromosomes have structural or numerical abnormalities. The reader is referred to Turek and Reijo Pera (2002) for a comprehensive review of such disorders. The postulation that deletions in the long arm of the Y chromosome cause azoospermia was made over three decades ago (Tiepolo et al, 1976). Based on cytogenetic analysis, this theoretic region was termed the *azoospermia factor* (AZF). Currently, the positional patterns of deletions (termed *microdeletions*) in the AZF region are used to subdivide this region into AZFa, AZFb, and AZFc subregions (Vogt et al, 1996). Regional deletions of the Y chromosome, termed *Yq microdeletions*, occur in 6% to 8% of severely oligospermic men and in 15% of azoospermic men (Reijo et al, 1996). Taken together, such deletions are the most commonly defined molecular cause of male infertility (Kostiner et al, 1998).

There is emerging literature addressing the prognostic value of specific AZF deletions. In sperm to partial and complete AZFc-deletion patients, in whom sperm is often found on semen analysis or testis biopsy, the chance of finding ejaculated or testis sperm in men with complete AZFa or AZFb deletions is highly unlikely (Hopps et al, 2003). Complete AZFa deletions are associated with germ cell aplasia or Sertoli cell–only histology. In general, complete AZFb deletions are associated with maturation arrest at the primary spermatocyte (early) or spermatid (late) stages. AZFc deletions are associated with hypospermatogenesis or a Sertoli cell–only pattern with foci of spermatogenesis. Sperm have been detected in ejaculates of men with presumed and confirmed partial AZFa and AZFb deletions (Foresta et al, 2001). Similarly, ejaculated sperm in men with AZFa + b, and AZFb + c deletions (presumably partial deletions) has also been reported, but the finding of AZFa – c deletions has been associated with azoospermia and no sperm on testis biopsy.

More recently, it has become clear that the X chromosome is also important for spermatogenesis, first postulated in rodent studies. In 2001, Wang and colleagues reported on a systematic search for genes expressed exclusively in mouse spermatogonia (Wang et al, 2001). Twenty-five genes were identified by complementary DNA (cDNA) subtraction, of which 10 localized to the X chromosome, suggesting that the X chromosome may have a key

role in premeiotic stages of spermatogenesis. A recent comparison of the mouse and human X chromosomes suggests that this chromosome may lead a double life and contribute significantly to both human male and female fertility (Mueller et al, 2013). Mutation studies of X-linked genes in male infertility patients have identified the SOX3 gene (sex determining region Y box 3) and the FATE gene as two potential candidate fertility genes (Olesen et al, 2003; Raverot et al, 2004). In the future, mutations in these and other X chromosome genes have the potential to define many currently unexplained cases of male infertility.

Genetics and Paternal Age

Age-Related Sperm Chromosomal Anomalies. The aneuploidy status and polyploidy status of sperm were first investigated owing to concern that advanced paternal age was associated with increased cases of trisomy, especially trisomy 21 or Down syndrome, in offspring. With fluorescence in situ hybridization (FISH) technology, subtle paternal-age effects on sperm aneuploidy are now evident. The paternal age effect appears to increase the fraction of sperm with sex chromosomal aneuploidies (Wyrobek et al, 1996). However, there is little evidence to support a paternal age–related increase in aneuploid births, except for possibly trisomy 21 and disomy 1 (very rare). Examining sperm chromosome structural abnormalities, Martin and Rademaker (1987) found that a significant linear relationship exists between paternal age and the frequency of structural anomalies in sperm ($r=0.63$). One explanation for this association may be that continued cell division during spermatogenesis places germ cells at risk for chromosomal injury, especially with advanced paternal age. Except for reciprocal translocations, however, there is little evidence to indicate that this association leads to an increased frequency of offspring with de novo structural chromosomal anomalies.

Age-Related Sperm Genetic Mutations. Single gene defects in sperm result from errors in DNA replication. To date, it has been difficult to assess the presence or absence of such defects in sperm. However, the effect of advanced paternal age on conditions in offspring associated with single-gene deletions is clear. These disorders are listed in Box 22-1 and consist of autosomal dominant diseases that have known associations with advanced paternal age. They are termed *sentinel phenotypes* because they are disorders of significant

BOX 22-1 Genetic Disorders in Offspring Associated with Advanced Paternal Age

- Achondroplasias
- Aniridia
- Apert syndrome
- Bilateral retinoblastoma
- Crouzon syndrome
- Fibrodysplasia ossificans
- Hemophilia A
- Lesch-Nyhan syndrome
- Marfan syndrome
- Neurofibromatosis
- Oculodentodigital syndrome
- Polycystic kidney disease
- Polyposis coli
- Progeria
- Treacher Collins syndrome
- Tuberous sclerosis
- Waardenburg syndrome
- Schizophrenia (postulated)
- Bipolar disorder (postulated)
- Autism (postulated)

frequency and low fitness, and stem from highly penetrant mutations. One mechanism for the development of new single-gene mutations with age implicates the characteristic and continuous process of spermatogonial cell division in spermatogenesis. By puberty, 30 cell divisions of spermatogonia have occurred, resulting in a large pool of undifferentiated cells. After puberty, 23 divisions per year occur in these cells. The simple fact that the spermatogonia of older men have undergone numerous cell divisions may make them more likely to harbor errors in DNA transcription, the source of single-gene defects. Formal risk estimates exist for the contribution of advanced paternal age to autosomal dominant mutations: In men younger than 29 years, the risk of a mutation occurring in offspring is 0.22 per 1000 births. This risk doubles (0.45 per 1000) at paternal ages 40 to 44, and then climbs to 3.7 per 1000 births at ages older than 45 (Friedman, 1981).

KEY POINTS: TESTIS

- The testis contains 250 meters of seminiferous tubules and 700 million Leydig cells in the young adult.
- Spermatogenesis occurs in stages, cycles, and waves to ensure constant sperm production.
- Genes on the X, as well as the Y, chromosome govern spermatogenesis and contribute to male infertility.
- With paternal age, there are increases in structural chromosomal abnormalities in sperm and autosomal dominant mutations leading to sentinel phenotypes in offspring.

EPIDIDYMIS

Gross Architecture

The epididymis is a comma-shaped organ located along the posterolateral surface of the testis. Passage through the epididymis induces many changes to newly formed sperm, including gains in functional motility, and alterations in surface charge, membrane proteins, immunoreactivity, phospholipids, fatty acid content, and adenylate cyclase activity. These changes improve cell membrane structural integrity, increase fertilization ability, and improve motility. Spermatozoa within the testis have very poor or no motility. They become progressively motile and functional only after traversing the epididymis. The transit time of sperm through the epididymis is thought to take 12 days in humans (Johnson and Varner, 1988).

The epididymis is a tubule or duct that is 3 to 4 meters in length and is tightly coiled and encapsulated within the sheath of connective tissue of the tunica vaginalis (Lanz and Neuhauser, 1964; Turner et al, 1978). Extensions from the sheath enter interductal spaces and form septa that divide the duct into histologically characteristic regions (Kormano and Reijonen, 1976). Anatomically, these are classically divided into three regions: caput or head, corpus or body, and cauda or tail (Fig. 22-16). The caput epididymis consists of 8 to 12 ductuli efferentes from the testis. The lumen of the ductuli efferentes is large and somewhat irregular in shape near the testis, becoming narrow and oval near the junction with the ductus epididymis. Distal to this junction, the duct diameter increases slightly and thereafter remains constant in the corpus epididymis. In the bulky cauda epididymis, the tubule diameter enlarges substantially and acquires an irregular shape. Progressing distally, the tubule gradually assumes the characteristic appearance of the vas deferens.

Vascular and Lymph Supply

In humans, the caput and the corpus epididymis receive arterial blood from a branch of the testicular artery (see Fig. 22-7). It subsequently divides into superior and inferior epididymal branches (MacMillan, 1954). The epididymis also receives blood from

Figure 22-16. Drawing of the human epididymis showing regionalization of the ductal epithelium and muscle layer. Epididymal segment locations are shown in cross section and are identified by number. (From Baumgarten HG, Holstein AF, Rosengren E. Arrangement, ultrastructure, and adrenergic innervation of smooth musculature of the ductal efferentes, ductus epididymidis, and ductus deferens in man. *Z Zellforsch Mikrosk Anat* 1971;120:37.)

branches of the deferential arteries (artery of the vas deferens), and collateral vessels connect the deferential artery to the testicular blood supply. The cauda epididymis is supplied by branches of the deferential artery. The deferential and cremasteric arteries serve as collateral sources to the epididymis, when the main testicular artery is obstructed or ligated. The arterial branches within the epididymis enter along septa formed from the connective tissue sheath. These vessels coil extensively before transforming into the straight vessels of the microvascular bed (Kormano and Reijonen, 1976). Microvascularization density varies significantly along the length of the epididymis, with the proximal caput containing the densest subepithelial capillary network, and the more distal segments harboring less dense vascularization. From animal studies, the epididymal capillary network is under hormonal control. For example, in rabbits, bilateral hormonal castration results in progressive deterioration and eventual disappearance of the epididymal capillary network (Clavert et al, 1981). It is not clear whether vascularization in the human epididymis is similarly controlled.

According to MacMillan (1954), venous drainage from the corpus and cauda epididymis joins to form the vena marginalis epididymis of Haberer. These veins drain into the pampiniform plexus through the vena marginalis testis, or through the cremasteric or deferential veins. Lymphatic drainage of the epididymis occurs through two routes (Wenzel and Kellermann, 1966). Lymph from the caput and corpus epididymis is removed through the same route as that described for the testis. These vessels course beside the internal spermatic vein and ultimately terminate in the preaortic

nodes. Lymph vessels from the cauda epididymis join those draining the vas deferens and terminate in the external iliac nodes.

Innervation

The innervation of the human epididymis is derived primarily from the intermediate and inferior spermatic nerves that arise from the superior portion of the hypogastric plexus and pelvic plexus, respectively (Mitchell, 1935). The ductuli efferentes and the proximal segments of the epididymis are sparsely innervated by sympathetic fibers (Baumgarten and Holstein, 1967; Baumgarten et al, 1968). In these regions, the fibers are observed in a peritubular plexus and are principally associated with blood vessels. Many more fibers are observed in the midcorpus epididymis, and their density increases progressively with progression along the epididymis, coincident with the appearance and proliferation of smooth muscle cells in these areas (Baumgarten et al, 1971). The distribution of contractile cells and sympathetic nerves within the epididymis may explain the rhythmic peristaltic movements of the ductuli efferentes and initial epididymal segments, as well as the intermittent contractile activity of the cauda epididymis and the vas deferens during emission (Risely, 1963). These physiologic contractions are critical to the movement of sperm through the epididymis.

Cytoarchitecture

Epididymal Epithelium

The histology of the human epididymis has been reviewed by Holstein (1969) and Vendrely (1981). It consists of two main cell types: **principal cells** and **basal cells** (seen at low ultrastructural magnification in Figure 22-17). Principal cells vary in height along the length of the epididymis owing to the length of stereocilia (microvilli, not cilia). In general, tall stereocilia (120 μm) are found in the proximal epididymis, and smaller or shorter stereocilia (50 μm) are observed in more distal regions. The nuclei in principal cells are elongated and often possess large clefts and one or two nucleoli. Consistent with the idea that principal cells carry out both absorptive and secretive processes, their cellular apices have numerous coated pits, micropinocytotic vesicles, multivesicular bodies, irregularly shaped membranous vesicles, and an extensive Golgi apparatus. Because these cytologic features vary along the length of the epididymis, it suggests that there is varying absorptive and secretory capacity along the length of the duct (Vendrely and Dadoune, 1988).

There are far fewer basal cells than principal cells lining the epididymal epithelium, and they are dispersed among the more numerous principal cells. Tear-shaped basal cells rest on the basal lamina and extend toward the lumen, their apices forming threads between adjacent principal cells. They are thought to be derived from macrophages. Unlike the principal cells, the morphology of basal cells remains relatively constant throughout the epididymal duct. They are thought to be the precursors of principal cells.

The epithelium of the epididymis exhibits regional differences along its length. Within the epididymis proper, the epithelium is pseudostratified and consists of principal and basal cells as described earlier. Proximally, at the junction of the rete testis and ductuli efferentes, there is a distinct transition from a low to a high cuboidal epithelium. The epithelium in the ductuli efferentes consists of ciliated and nonciliated cells (Holstein, 1969). The ciliated cells conduct sperm from the efferent ducts into the epididymis. The nonciliated cells with protruding apices are likely secretory in nature and predominate in the proximal ductuli efferentes (Vendrely, 1981). Other nonciliated cells have microvilli suggestive of resorptive activity and predominate in the distal ductuli efferentes. Both nonciliated and ciliated cells are joined apically through junctional complexes. This suggests the existence of a blood-epididymis barrier analogous to the blood-testis barrier (Suzuki and Nagano, 1978; Hoffer and Hinton, 1984). Although not as dense as the blood-testis barrier, the blood-epididymis barrier extends from the caput to the cauda epididymis and may play an important role

Figure 22-17. Electron micrograph of a human epididymis in cross section. Major components of the luminal epithelium are principal cells (1), basal cells (2), stereocilia (3), and myofilaments (4). Magnification approximately $\times 1800$. (From Holstein AF. In: Hafez ESE, editor. Human semen and fertility regulation in men. St. Louis: Mosby; 1976.)

in influencing the composition of fluid within different segments of the epididymal lumen (Turner, 1979).

Epididymal Contractile Tissue. Peripheral to the basal lamina of the ductuli efferentes and the epididymal tubule are various contractile cells (Baumgarten et al, 1971) (see Fig. 22-17). In the ductuli efferentes (distal regions of the caput and the proximal corpus epididymis), the contractile cells form a loose layer, two to four cells deep, around the tubule. These cells contain myofilaments and are connected by numerous nexus-like junctions. In the distal corpus epididymis, there are larger contractile cells with fewer nexus-like intracellular junctions that resemble smooth muscle cells. In the cauda epididymis, the thin contractile cells are replaced by thick smooth muscle cells that form three layers—the outer two layers oriented longitudinally and the central layer circularly. This distal contractile layer increases in thickness as it forms the vas deferens. The contractile tissue throughout the epididymis is likely involved in sperm transport.

Epididymal Function

Described variations in the anatomy and histology of the epididymal tubule from the caput to cauda regions suggest that the epididymis is actually several different functional tissues (Vendrely, 1981). It is clear that sperm transport and storage, fertilizing ability, and motility maturation are several consequences of epididymal passage. This is addressed more fully in reviews by Robaire and Hermo (1988) and Moore and Smith (1988).

Sperm Transport

Sperm transport through the human epididymis has been calculated to take from 2 to 12 days (Johnson and Varner, 1988). Sperm transit time through the caput-corpus epididymis is roughly similar to the transit time through the cauda epididymis and is more likely related to daily testicular sperm production rather than a man's age or the frequency of ejaculation (Amann, 1981; Johnson and Varner, 1988). In one study, sperm epididymal transit time averaged 2 days in men with a high daily rate of sperm production, compared with 6 days in men with low daily sperm production (Johnson and Varner, 1988). Although the frequency of sexual activity does not affect sperm transit time through the caput and corpus epididymis, "recent emissions" can reduce transit time through the cauda epididymis by 68% (Amann, 1981).

Because normal human testicular sperm are immotile as they enter the epididymis, and remain relatively immotile within the caput, mechanisms other than sperm motility must exist to transport sperm through the epididymis. Animal studies have been very revealing in this regard (Bedford, 1975; Hamilton, 1977; Courrot, 1981; Jaakkola and Talo, 1982; Jaakkola, 1983). Initially, sperm are carried into the ductuli efferentes by rete testis fluid, and fluid flow is facilitated by fluid resorption by ductal epithelial cells mediated by the estrogen receptor. Motile cilia and myoid cell contractions within the ductuli efferentes also assist with sperm movement. Within the epididymis proper, the principal mechanism responsible for sperm transport is likely the spontaneous, rhythmic contraction of the contractile cells surrounding the epididymal duct.

Sperm Storage

After migrating through the caput and corpus epididymis, sperm are retained in the cauda epididymis for varying lengths of time, depending on the frequency of sexual activity. In men 21 to 55 years of age, an average of 155 to 209 million sperm are present in each epididymis (Amann, 1981; Johnson and Varner, 1988), and approximately half are stored in the caudal region.

Spermatozoa stored in the cauda epididymis, unlike testicular sperm, are capable of progressive motility and are able to fertilize eggs. The exact amount of time that sperm can remain fertile within the epididymis is unclear, but animal studies have shown that sperm can remain viable for several weeks after vas deferens ligation (Hammond and Asdell, 1926; Young, 1929). However, it is also clear that sperm fertility measured *in vivo* diminishes when sperm are maintained in the epididymis for prolonged periods of time (Cooper and Orgebin-Crist, 1977; Cuasnicu and Bedford, 1989). In humans, sperm aging as a result of extended epididymal transit time and prolonged storage may contribute to reduced fertility (Johnson and Varner, 1988).

The exact fate of unejaculated epididymal sperm is unknown. In animals, sperm are lost through spontaneous seminal discharge, through oral self-cleaning (Martan, 1969), in urine (Lino et al, 1967), or by epididymal reabsorption (Amann and Almquist, 1961). Phagocytosis of spermatozoa by macrophages (spermio-phages) within the epididymal lumen has been observed in humans after ligation of the vas deferens (Alexander, 1972). However, whether this mechanism can remove large numbers of spermatozoa from the epididymis of unvasectomized men is unclear.

Sperm Maturation

Sperm Motility. Sperm gain an increased capacity for motility with migration through the epididymis. This is observed as both a change in the pattern of motility and as an increase in the proportion of sperm exhibiting "mature" motility patterns. Bedford and coworkers (1973) first observed that the majority of sperm from the ductuli efferentes, when placed in culture medium, are immotile or show only weak, twitching movement. Occasionally, they also observed sperm showing "immature" tail movements characterized by "thrashing" beats in wide arcs that result in little

forward progression. The proportion of sperm with this immature motility pattern increased within the initial epididymal segment. However, in the corpus region, the proportion of sperm exhibiting this motility pattern decreased. Within the corpus region, there was an increase in the fraction of sperm with a "mature" motility pattern characterized by high-frequency, low-amplitude beats that result in progressive motility (Fig. 22-18). Within the cauda epididymis, more than 50% of sperm had a mature motility pattern, with the remainder either immotile or showing the immature motility patterns described earlier. Moore and colleagues (1983) also formally demonstrated the increased capacity of human sperm to show progressive forward motility with epididymal transit. When placed in buffer *in vitro*, increasing proportions of sperm were motile as they progressed from the efferent ducts to the caput, proximal corpus, distal corpus, and cauda epididymis (Fig. 22-19).

The relative importance of overall epididymal contact time versus region-specific maturation to gains in mature sperm motility patterns is unknown. Animal studies indicate that motility maturation may, in part, be an intrinsic sperm process that occurs independent of specific epididymal interactions. For example, although hamster and rabbit sperm are in general immotile within the caput epididymis, motile sperm are found in this region (albeit developing motility far more slowly and persisting for shorter periods than in the normal system) after epididymal duct ligation within the corpus region (Orgebin-Crist, 1969; Horan and Bedford, 1972). Human studies in obstructed patients with congenital absence of the vas deferens or epididymal obstruction also frequently report poor motility in spermatozoa aspirated from the distal epididymis, and better sperm motility in the proximal epididymis (Silber, 1989; Matthews et al, 1995). When combined, these observations suggest that spermatozoa are able to develop motility based on contact time with the proximal epididymal epithelium. However, this maturation process may not be the same as that which occurs through sperm interaction with the epididymis during migration through all ductal regions.

Sperm Fertility. Testicular sperm are incapable of fertilizing eggs unless injected into them with micromanipulation (Orgebin-Crist, 1969; Bedford, 1974; Yanagimachi, 2005). In most animals, the ability of sperm to fertilize eggs is acquired gradually as the sperm pass through the distal epididymis (see Fig. 22-19). Indeed, it has

Figure 22-18. Patterns of tail movement of human epididymal sperm. **A,** The pattern shown by sperm taken from the proximal epididymis is characterized by high-amplitude, low-frequency beats producing little forward movement. **B,** In contrast, tail movement in a large proportion of sperm from the cauda epididymis is characterized by low-amplitude, rapid beats with forward progression. (From Bedford JM, Calvin HI, Cooper GW. The maturation of spermatozoa in the human epididymis. *J Reprod Fertil* 1973;18:199–213.)

Figure 22-19. Sperm fertility maturation in the human epididymis. Sperm fertilizing ability was assessed using zona pellucida-free hamster eggs and by changes in motility. (From Bedford JM. The bearing of epididymal function in strategies for in vitro fertilization and gamete intrafallopian transfer. *Ann N Y Acad Sci* 1988;541:284–91.)

been shown in rabbits that sperm from the caput, corpus, and cauda epididymis can fertilize 1%, 63%, and 92% of rabbit eggs, respectively (Orgebin-Crist, 1969). Human in vitro experiments using zona pellucida-free hamster eggs have corroborated these findings (Moore et al, 1983). In a study that assessed the fertilizing capacity of human epididymal sperm, Hinrichsen and Blaquier (1980) demonstrated that although sperm from the proximal epididymis are able to bind to zona-free eggs, only sperm from the cauda epididymis can both bind and penetrate eggs. Thus sperm fertility maturation is, for the most part, achieved at the level of the late corpus or early cauda epididymis.

Recent clinical observations, however, challenge the idea that fertility maturation requires sperm migration through the entire epididymis. Indeed, patients with epididymal obstruction or congenital absence of the vas deferens can achieve natural pregnancies after vasoepididymostomy at the level of the ductuli efferentes (Schoysman and Bedford, 1986; Silber, 1989). This suggests that obstruction induces proximal skewing of the maturation sequence along the epididymal duct or that there may be a reduced flow of sperm through the epididymis after such bypass procedures, allowing more contact time and sperm maturation (Orgebin-Crist, 1969; Turner and Roddy, 1990). Despite this observation, it is generally believed that the likelihood of fertility is greater as the surgical anastomosis is performed more distally in the epididymis (Thomas, 1987). Additional findings from the reversal of older vasectomies (>15 years of obstruction) suggest that although post-operative ejaculated sperm concentrations are maintained after reversals with prolonged obstructive intervals, sperm motility is significantly decreased. This indicates that acquired epididymal dysfunction resulting from prolonged blockage may play an important role in the fertility potential of men after vasectomy reversal (Mui et al, 2014).

Sperm Biochemical Changes. Sperm undergo many biochemical changes with passage through the epididymis (Brooks, 1983). Epididymal sperm transit induces a net negative surface membrane

charge (Bedford et al, 1973), and sperm membrane sulfhydryl groups oxidize to disulfide bonds, improving sperm structural rigidity necessary for progressive motility and egg penetration (Bedford et al, 1973; Reyes et al, 1976). Other post-testicular modifications of sperm membranes include changes in sperm lectin-binding properties (Courtens and Fournier-Delpech, 1979; Olson and Danzo, 1981), phospholipid and lipid content (Nikolopoulou et al, 1985), glycoprotein composition (Brown et al, 1983), immunoreactivity (Tezón et al, 1985), and iodination characteristics (Olson and Danzo, 1981). Overall, these membrane modifications during epididymal passage may enhance sperm adherence to the egg zona pellucida (Orgebin-Crist and Fournier-Delpech, 1982; Blobel et al, 1990). Sperm also undergo numerous metabolic changes during epididymal transit (Dacheux and Paquignon, 1980). These include an increased capacity for glycolysis (Hoskins et al, 1975), changes in intracellular pH and calcium content, modification of adenylate cyclase activity (Casillas et al, 1980), and alterations in cellular phospholipid and phospholipid-like fatty acid content (Voglmayr, 1975).

Regulation of Epididymal Function

Sperm changes within the epididymis are likely influenced by fluids and secretions within the epididymal lumen (Robaire and Hermo, 1988; Blaquier et al, 1989). The biochemical composition of epididymal fluid differs from that of serum and also shows regional differences in osmolarity, electrolyte content, and protein composition (Robaire and Hermo, 1988). These differences are likely the consequence of variations in vascularization, blood-epididymis barrier activity, and selective absorption and secretion of substances such as glycerylphosphorylcholine (GPC), carnitine, and sialic acids along the epididymal duct. Proteins within epididymal fluid that are known to have physiologic effects on sperm in vitro include forward motility protein (Brandt et al, 1978), sperm survival factor (Morton et al, 1978), progressive motility sustaining factor (Sheth et al, 1981), sperm motility-inhibiting factor (Turner and Giles, 1982), acidic epididymal glycoprotein (Pholpramool et al, 1983), and the EP2-EP3 proteins that induce sperm binding to zona pellucida (Cuasnicu et al, 1984; Blaquier et al, 1988). Thus, variations in epididymal tubule fluid characteristics play an important role in sperm maturation during epididymal transit. It is not surprising, then, that the epididymis is a potentially important source of sperm dysfunction and male infertility.

Epididymal function is hormonally regulated. Testosterone and DHT are found in very high concentrations within the epididymis and do not show regional gradients in androgen levels (Leinonen et al, 1980). This suggests the importance of androgens for epididymal function (Brooks and Tiver, 1983). In animals, castration results not only in the loss of androgen-dependent epididymal proteins but also losses in epididymal weight, changes in luminal histology, and alterations in the synthesis and secretion of epididymal fluid GPC, carnitine, and sialic acid. Ultimately, the castrated epididymis loses the ability to sustain sperm motility, fertility maturation, and sperm storage capacities, processes that are reversed with androgen replacement.

Compared with other accessory sex glands, the epididymis requires relatively higher levels of androgen to maintain its structure and function (Prasad and Rajalakshmi, 1976). Androgen effects on the epididymis are mediated mainly through DHT, the primary androgen in epididymal tissue extracts (Pujol et al, 1976), and/or 5 α -androstane-3 α , 17 β -diol (3 α -diol) (Orgebin-Crist et al, 1975). Indeed, this is corroborated by the fact that the enzymes Δ 4-5 α -reductase (catalyzes DHT formation from testosterone) and 3 α -hydroxysteroid dehydrogenase (converts DHT to 3 α -diol), which produce testosterone metabolites, are also found in the human epididymis (Kinoshita et al, 1980; Larminat et al, 1980). It may also help to explain the recent observation that the clinical use of 5 α -reductase inhibitors is associated with impaired semen quality (Amory et al, 2007).

Epididymal function is also influenced by temperature (Foldes and Bedford, 1982; Wong et al, 1982). Chronic exposure

of the epididymis to elevated temperatures, for example by placing them within the abdomen, results in the loss of sperm storage and electrolyte transport functions. The effect of temperature on epididymal function may help explain how varicocele and cryptorchidism affect male infertility. Abnormalities in epididymal myoid cell contractility may also influence epididymal function. In the rat, partial surgical denervation of the epididymis results in an abnormal accumulation of sperm within the cauda epididymis and a decrease in the swimming speed of sperm (Billups et al, 1990). These findings have implications for infertility from neuropathic causes such as spinal cord injury and diabetes mellitus.

KEY POINTS: EPIDIDYMIS

- The epididymis consists of principal cells with absorptive and secretory function, basal cells derived from macrophages, and contractile cells that facilitate sperm transport.
- During epididymal passage, sperm mature by gaining progressive motility and the ability to bind to and penetrate the egg zona pellucida.
- Epididymal function is temperature and androgen (mainly DHT) dependent, important considerations for cryptorchidism, varicocele, and 5 α -reductase use.

DUCTUS (VAS) DEFERENS

Gross Architecture

The vas deferens is a tubular organ derived from the mesonephric (wolffian) duct. In humans, the vas deferens is 30 to 35 cm long, beginning at the cauda epididymis and terminating in the ejaculatory duct, medial to the seminal vesicle and posterior to the prostate. It is classically divided into five regions: (1) the sheathless epididymal segment contained within the tunica vaginalis, (2) the scrotal segment, (3) the inguinal segment, (4) the retroperitoneal or pelvic portion, and (5) the ampulla (Lich et al, 1978). In cross section, the vas deferens consists of an outer adventitial connective tissue sheet containing blood vessels and small nerves, a muscular coat that consists of a middle circular layer surrounded by inner and outer longitudinal muscle layers, and an inner mucosal layer with an epithelial lining (Neaves, 1975). The outer diameter of the vas deferens varies from 1.5 to 3 mm, and the lumen of the unobstructed vas deferens varies from 200 to 700 μ m in diameter (Midleton et al, 2009).

The vas deferens receives its blood supply from the deferential artery, a branch of the superior vesical artery. Venous drainage corresponds to arterial supply. The vas deferens receives innervation from both the sympathetic and the parasympathetic nervous systems (Sjostrand, 1965). The cholinergic supply does not appear important for motor activity of the vas deferens (Baumgarten et al, 1975). There is a rich supply of sympathetic adrenergic nerves derived from hypogastric nerve coursing via the presacral nerve (Batra and Lardner, 1976; McConnell et al, 1982). Adrenergic nerve fibers have been observed in all three layers of the vas muscularis, with the greatest concentration in the outer longitudinal layer (McConnell et al, 1982). The vas deferens also receives a short adrenergic nerve (Sjostrand, 1965) and has an abundance of ligand-gated, purinergic receptors in its smooth muscle membranes, suggesting sympathetic and purinergic cotransmission in sperm transport and ejaculation (Gur et al, 2007). Neurons containing other neurotransmitters, including neuropeptide Y, enkephalin, galanin, somatostatin, vasoactive intestinal polypeptide, and nitric oxide, have also been identified; however, their role in vas deferens function is unknown (Dixon et al, 1998). It is interesting to note that observations from human vas deferens specimens obtained at vasovasostomy after vasectomy show a marked reduction in the density of muscular noradrenergic and subepithelial secretomotor nerves in testicular compared with abdominal segments. These

changes may influence subsequent sperm transport processes, and hence procedural success, after vasectomy reversal (Dixon et al, 1998).

Cytoarchitecture

The human vas deferens is lined by pseudostratified epithelium (Paniagua et al, 1981). The height of the epithelium decreases along the length of the vas deferens from the testis to the seminal vesicle. In addition, the longitudinal epithelial folds are simpler near the testis and become more complex distally. The pseudostratified epithelium vasal lining is composed of basal cells and three types of tall, thin columnar cells (Hoffer, 1976; Paniagua et al, 1981). The columnar cells, extending from the epithelial base to the lumen, include principal cells, but also pencil cells and mitochondria-rich cells. All columnar cells exhibit stereocilia and irregular convoluted nuclei. Principal cells are the most frequent columnar cell type in the proximal vas deferens, whereas both pencil cells and mitochondria-rich cells increase in density distally. The thickness of the total muscle layer gradually decreases along the length of the vas deferens. This complex cytoarchitecture strongly suggests that the vas deferens is more than simply a passive conduit for sperm transport.

Vas Deferens Function

Sperm Transport

Sperm transport through the vas deferens is influenced by several physiologic processes. First, the human vas deferens exhibits spontaneous motility (Ventura et al, 1973). It also has the capacity to respond when stretched (Bruschini et al, 1977). Finally, fluid within the vas deferens can be propelled into the urethra by strong peristaltic contractions elicited either by electrical stimulation of the hypogastric nerve (Bruschini et al, 1977) or by adrenergic neurotransmitters (Bruschini et al, 1977; Lipshultz et al, 1981). This suggests that immediately before emission, with sympathetic stimulation, sperm is rapidly transported from the distal epididymis through the vas deferens to the ejaculatory duct. This rapid transport is consistent with the vas deferens having the highest muscle-to-lumen ratio (approximately 10:1) of any hollow viscus in the body.

Sperm reserves in the vas deferens have been estimated at approximately 130 million, suggesting that a significant proportion of human ejaculated sperm is stored in the vas deferens (Amann and Howards, 1980). In addition, vasal sperm quality, as assessed from fertile men at the time of vasectomy, is very similar to that of the ejaculate, with 71% motility and 91% viability (Bachtell et al, 1999). In the rabbit, it has been shown that during sexual rest, epididymal sperm are transported through the vas deferens and leak into the urethra in small amounts (Prins and Zaneveld, 1979, 1980a, 1980b). This suggests that the vas deferens is involved in ridding the epididymis of excess, stored sperm. On sexual stimulation, rabbit sperm are transported through the vas deferens similar to humans. After sexual stimulation, however, the vas deferens contents are propelled proximally toward the epididymis because the distal vas deferens contracts with greater amplitude, frequency, and duration than the proximal segment (Prins and Zaneveld, 1980a). Notably, with prolonged sexual rest, excess epididymal sperm are once again transported distally, supporting the idea that the vas deferens is important for sperm transport and for maintenance of epididymal sperm reserves.

Absorption and Secretion

Based on its cytoarchitecture, the human vas deferens likely has both absorptive and secretory functions (Hoffer, 1976; Paniagua et al, 1981). The principal cells are typical of cells that synthesize and secrete glycoproteins (Bennett et al, 1974; Gupta et al, 1974). The stereocilia, apical blebbing, and primary and secondary

lysosomes within principal cells are also characteristic of cells involved in absorptive function (Friend and Farquhar, 1967; Murakami et al, 1988). Lastly, spermophagy by epithelial cells in the ampullary vas deferens has been observed with scanning electron microscopy in both men and monkeys (Murakami et al, 1988). It is important to note that normal vas deferens function is likely to be androgen dependent because the vas deferens actively converts testosterone to DHT (Dupuy et al, 1979). Castration causes atrophy of—and testosterone treatment, restoration of—monkey vas cytoarchitecture (Dinakar et al, 1977), and spontaneous and α - and β -adrenergic-stimulated contractions of the rat vas deferens are altered by castration (Borda et al, 1981). Thus, although once thought to be a simple muscular conduit for sperm, the vas deferens is now viewed as a complex reproductive organ.

SEMINAL VESICLE AND EJACULATORY DUCTS

Gross Architecture and Cytoarchitecture

Seminal Vesicle

In the adult, the seminal vesicles are paired, elongated, hollow viscous organs located posterior to the prostate and bladder. Each seminal vesicle is 5 to 7 cm long and up to 1.5 cm wide. Each seminal vesicle actually consists of a tubule that is 15 cm long and highly coiled and convoluted. The tubule itself is composed of three layers: The inner lining is a moist and folded mucous membrane; the middle layer is largely collagenous; and the outer layer consists of circular and longitudinal muscle layers that constitute 80% of the wall thickness (Nguyen et al, 1996). The mucosa of the seminal vesicle, mainly nonciliated, pseudostratified columnar or cuboidal cells, is notable for many thin, complicated folds that produce numerous crypts. The excretory duct of the seminal vesicle opens into the ampullary vas deferens as it enters the prostate gland.

The blood supply to the seminal vesicle arises from the internal iliac artery and inferior vesicular artery through the prostatovesicular branch (Clegg, 1955). The prostatovesicular artery can also arise from the superior vesicular artery or from the pudendal artery. Most commonly, the prostatovesicular artery has anterior and posterior branches that supply the respective surfaces of the seminal vesicle. The lymphatic drainage of the seminal vesicle is through the internal iliac lymph nodes. The seminal vesicles are innervated through sympathetic nerves from the superior lumbar and hypogastric nerves. Parasympathetic innervation occurs through the pelvic plexus.

Ejaculatory Ducts

The ejaculatory ducts are paired, collagenous, tubular structures that commence at the junction of the vas deferens and seminal vesicle, course through the prostate, and empty into the prostatic urethra at the verumontanum. Histologically, the ejaculatory ducts are a continuation of the seminal vesicle, except that the outer circular muscle layer does not extend into the ducts (Nguyen et al, 1996). There are three distinct anatomic regions to the ejaculatory duct: the proximal, extraprostatic portion; the middle intraprostatic segment; and a short distal segment incorporating the lateral aspect of the verumontanum in the urethra (Nguyen et al, 1996) (Fig. 22-20). Although the ejaculatory duct contains an outer muscular layer in its extraprostatic and intraprostatic segments, as the duct courses distally the outer muscular layer dissipates, and there is no valvelike, muscular “sphincter” at the ejaculatory duct orifice, as was once thought (Nguyen et al, 1996) (Fig. 22-21). Instead, urinary reflux is prevented and ejaculatory continence is maintained by the acute angle of duct insertion into the urethra. The inner epithelial layer of the ejaculatory ducts is also complex and folded and consists of simple and pseudostratified columnar cells. The ejaculatory ducts receive their blood supply from branches of the inferior vesical artery and are innervated through the pelvic plexus.

Figure 22-20. Schematic anatomy of the human ejaculatory duct complex. *A*, Proximal; *B*, intraprostatic or middle; and *C*, distal ejaculatory duct regions. The inset shows how the muscle layer thins out in the middle segment. (From Nguyen HT, Etzell J, Turek PJ, et al. Normal human ejaculatory duct anatomy: a study of cadaveric and surgical specimens. *J Urol* 1996;155:1639-42.)

Seminal Vesicle and Ejaculatory Duct–Unit Function

Animal studies suggest that the seminal vesicle and ejaculatory ducts are functionally similar to the bladder and urethra (Turek et al, 1998). The seminal vesicle is a contractile, compliant, smooth muscular organ with dynamic properties analogous to those of the bladder, and the ejaculatory ducts serve as a urethra-like conduit. This theory allows the classification of ejaculatory duct obstruction into two types of disorders, analogous to bladder outlet obstruction: (1) obstruction resulting from physical blockage of the ducts, similar to bladder outlet obstruction, and (2) “functional” obstruction of the seminal vesicle, similar to voiding dysfunction caused by bladder myopathy. In addition, this has implications for the diagnosis of ejaculatory duct disorders because “static” anatomic imaging, such as transrectal ultrasonography, may not be sufficient to differentiate between these disorders, and medications and conditions (such as diabetes) might predispose the system to seminal vesicle dysfunction (Smith et al, 2008).

Figure 22-21. Human ejaculatory duct gross and microscopic anatomy from cadaver specimens. A, Sagittal section through the midline with pin in ejaculatory duct orifice and ejaculatory duct (ED) and veru (V), urethra (U), and prostate (P) visible. B, Microphotograph of the paired ejaculatory ducts in the middle intraprostatic segment showing the thick collagenous layer (C) surrounding the mucosa with a thin, outer muscular layer (M). (From Nguyen HT, Etzell J, Turek PJ, et al. Normal human ejaculatory duct anatomy: a study of cadaveric and surgical specimens. *J Urol* 1996;155:1639–42.)

Seminal Vesicle Function

The seminal vesicles secrete a significant proportion (80%) of the seminal fluid, and these secretions are found in later fractions of the ejaculate, after the sperm-rich epididymal and prostatic secretions. After ejaculation, sperm pass into and through the female cervical mucus and subsequently the uterus to enter the oviduct, where fertilization occurs. During residence in the female reproductive tract, sperm must undergo capacitation before oocyte fertilization. During capacitation, the acrosome reaction and development of hyperactivated motility occurs (Yanagimachi, 1994). It is not clear if prostatic or seminal vesicle secretions contribute to capacitation.

In fact, the exact physiologic role of seminal vesicle fluid is not clear, although in rodents it functions as a plug or barrier that reduces the chances for sperm from a subsequent male to fertilize the oocyte. Before ejaculation, semen is a liquid, and after all components mix with the seminal vesicle secretions, it coagulates. The major component of the coagulum is semenogelin I, a 52-kD protein expressed exclusively in the seminal vesicles (Robert et al, 1999). Through coagulating semen, seminal vesicle secretions may promote sperm motility, increase stability of sperm chromatin, and suppress immune activity in the female reproductive tract. The best-elucidated function of human semen appears to be its ability to provide antioxidative protection to sperm. Semen is rich in antioxidant enzymes, including glutathione peroxidase, superoxide dismutase, and catalase (Yeung et al, 1998). In addition, the antioxidant molecules taurine, hypotaurine, and tyrosine are present in high concentrations (van Overveld et al, 2000). Lipofuscin granules from dead epithelial cells give seminal vesicle secretions a yellow-white color. In addition, seminal vesicle secretions are alkaline and contain fructose, mucus, vitamin C, flavins, phosphoryl choline, and prostaglandins. High fructose levels provide nutrient energy for the sperm when studied in vitro. The mixing of seminal vesicle with prostatic secretions results in human semen having a mildly alkaline pH. Acidic ejaculate (pH <7.2) is associated with blockage or absence of seminal vesicles (Turek, 2005).

SPERMATOZOA

Anatomy and Physiology

The human spermatozoon is approximately 60 μm in length and is divided into three morphologic sections: head, neck, and tail (Fig. 22-22). The oval sperm head, about 4.5 μm long and 3 μm wide, contains a nucleus with highly compacted chromatin and an

KEY POINTS: VAS DEFERENS, SEMINAL VESICLE, AND EJACULATORY DUCTS

- The vas deferens is of wolffian (mesonephric) duct origin and serves to transport sperm from the cauda epididymis to the ejaculatory duct during seminal emission.
- The seminal vesicle and ejaculatory duct unit is analogous to the bladder and urethra and is subject to both physical blockage and functional disorders that result in infertility.

acrosome, a membrane-bound organelle that harbors enzymes required for penetration of the outer vestments of the egg before fertilization (Yanagimachi, 1978). The **sperm neck** maintains the connection between the sperm head and tail. It consists of the **connecting piece** and **proximal centriole**. The **axonemal complex** extends from the proximal centriole through the sperm tail. The **tail** harbors the **midpiece**, **principal piece**, and **endpiece** (Zamboni, 1992). The midpiece is 7 to 8 μm long and is the most proximal segment of the tail, terminating in the annulus. It contains the **axoneme**, with its characteristic microtubule arrangement, and surrounding **outer dense fibers** (Fig. 22-23). It also contains the **mitochondrial sheath**, which is helically arranged around the outer dense fibers. The outer dense fibers, rich in disulfide bonds, are not contractile proteins but are thought to provide the sperm tail with the elastic rigidity necessary for progressive motility (Okamoto and Clermont, 1990). Similar in structure to the midpiece, the principal piece has several columns of outer dense fibers that are replaced by the fibrous sheath. The fibrous sheath consists of **longitudinal columns** and **transverse ribs**. The sperm terminates in the endpiece, the most distal segment of the sperm tail, and contains axonemal structures and the fibrous sheath. Except for the endpiece region, the sperm is enveloped by a highly specialized plasma membrane that regulates the transmembrane movement of ions and other molecules (Friend, 1989).

The spermatozoon is a remarkably complex metabolic and genetic machine. The 75 sperm mitochondria that surround the axoneme contain enzymes required for oxidative metabolism and produce adenosine triphosphate (ATP), the primary energy molecule for the cell. Mitochondria are organelles that produce cellular energy and can also cause apoptotic cell death through the release of cytochrome *c*. Mitochondria are composed of outer and inner membranes. The inner membrane forms deep folds into the matrix, called the **cristae**, which make the surface area of the inner

membrane larger than that of the outer membrane. Five distinct respiratory chain complexes span the width of the inner membrane and are necessary for oxidative phosphorylation: nicotinamide adenosine diphosphate (NADPH) dehydrogenase, succinate dehydrogenase, cytochrome *bc1*, cytochrome *c* oxidase, and ATP synthase complexes. Contained within the matrix are citric acid cycle, fatty acid, and amino acid oxidative enzymes; newly made ATP; mitochondrial DNA (mtDNA); and ribosomes.

Figure 22-22. Diagram of a typical mammalian spermatozoon. The plasma membrane is omitted to illustrate the major cellular components. Cross-sectional insets show the orientation of the internal cell structures. (From Fawcett DW. The mammalian spermatozoon. *Dev Biol* 1975;44:394–436.)

Human mitochondria contain DNA (mtDNA) that is distinct from sperm nuclear DNA. mtDNA consists of a circular, histone-free chromosome of 16,569 base pairs of DNA arranged in a single heavy and single light strand and **encodes respiratory-chain-complex subunit proteins, mitochondrial rRNAs, and tRNAs used for protein synthesis.** These genes have no introns. mtDNA is also far more susceptible to mutations than is nuclear DNA (estimated 40 to 100 times higher). Reasons for this may include the fact that mitochondria are near respiratory-chain complexes and may be easily attacked by reactive oxygen species. **In addition, mtDNA is not coated with protective histones, and mitochondria have very limited DNA repair mechanisms (Hirata et al, 2002).** The fact that mitochondria rapidly accumulate mutations suggests the necessity of degrading all paternal mtDNA in the fertilized egg. This degradation is likely mediated by the small proteolytic polypeptide ubiquitin, which regulates proteolysis in many tissues (Sutovsky et al, 1999).

From animal studies, it is clear that the plasma membrane covering the sperm-head region harbors specialized proteins that participate in sperm-egg interaction (Saling, 1989). Indeed, carbohydrate-binding proteins on the sperm membrane interact with the species-specific ZP3 protein in the egg zona pellucida, resulting first in sperm binding to the zona and subsequently to induction of the acrosome reaction (Shabanowitz, 1990). Another sperm membrane protein, PH30, is present on testicular sperm, is modified during sperm migration through the epididymis, and functions as a fusion protein between the sperm and egg membranes at fertilization (Primakoff et al, 1987; Blobel et al, 1990).

Physiologically, the axoneme is the true motor assembly and requires 200 to 300 proteins for proper function. Among these, the “9 + 2” pattern of outer and inner doublets of microtubules is the best-understood component (see Fig. 22-23). The dynein proteins extend from one microtubule doublet to the adjacent doublet and form both the inner and outer arms of the axoneme. **The sperm axoneme contains the enzymes and structural proteins necessary for the chemical transduction of ATP into mechanical movement and motility.** Dynein is a large (2000 kD), Mg^{2+} -stimulated ATPase responsible for ATP-generated microtubule sliding that causes axonemal bending and, ultimately, sperm flagellar movement. The dynein structure has two or three globular, outer (heavy) chain heads (500 kD) joined to a common stem. The heads control movement along the microtubules. The inner (light) chain arms (14 to 120 kD) are the primary effectors of movement and are associated with the radial spokes of the dynein assembly. Sperm with outer arm mutants have reduced motility, and those with inner arm mutants have no motility. Radial links or spokes connect a microtubule of each doublet to the central inner doublet and consist of

Figure 22-23. The “9 + 2” sperm axonemal structure. **Left,** Schematic cross section of axoneme, demonstrating microtubule arrangement. **Right,** Electron micrograph of axoneme. A, outer doublet; B, inner central doublet; C, outer dynein arm; D, radial link.

a complex of proteins. The central inner doublet is surrounded by a ringlike helical sheath to which the radial links from the outer doublets are attached. Tektins are proteins associated with the outer microtubular doublets, and nexin links are proteins that connect the outer doublets to one another and maintain the cylindric axonemal shape.

The phenotype of defective sperm structure has been recognized as ciliary dyskinesia. Although infertility is the rule with ciliary dyskinesias, ejaculated sperm can be motile and sperm concentrations can be normal. With ICSI, clinical pregnancies and live births have been reported after use of affected sperm (Cayan et al, 2001). Because the inheritance is usually recessive, normal offspring are likely. In general, patients suspected of harboring sperm structural defects exhibit severely compromised sperm motility (<10%). Sperm electron microscopy can reveal ultrastructural or functional sperm abnormalities. Sperm structural abnormalities are currently categorized by Chemes (2000) as follows:

1. **Nonspecific flagellar anomalies.** This is the most frequent flagellar anomaly underlying severely low motility and shows a structural phenotype of random, heterogeneous, microtubular alterations. These anomalies can arise from correctable disorders such as varicocele, reactive oxygen species, and gonadotoxin exposure. There is no evidence of familial occurrence.
2. **Dysplasia of the fibrous sheath.** This condition is a systematic sperm abnormality, usually associated with near-complete or total immotility. It has a more homogenous and distinctive phenotype characterized by sperm fibrous sheath, axonemal, and periaxonemal distortions. A subset of these patients exhibit the classic ciliary dyskinesia (formerly *immotile cilia syndrome*), in which sperm immotility is associated with respiratory disease and dextrocardia. There is a strong familial incidence, suggesting that such conditions are genetic in origin.

KEY POINTS: SPERM

- Sperm are ciliated cells that possess a “9 + 2” axonemal structure that allows motility.
- It is estimated that 200 to 300 genes regulate sperm motility.
- Sperm motility defects, termed *ciliary dyskinesias*, are common and can be either correctable (nonspecific flagellar anomalies) or genetic (dysplasia of the fibrous sheath).
- Human sperm mtDNA is a circular, histone- and intron-free DNA ring that encodes for respiratory-chain-complex proteins and is very susceptible to mutations.

SUMMARY

Spermatogenesis is a remarkably intricate and complex process that is driven by precisely regulated secretions of GnRH, LH, and FSH from the HPG axis. Perturbations in this hormonal milieu are common causes of male infertility. Sperm production in the testis functions optimally at 2°C to 4°C below body temperature and

generates a mature human sperm in 64 days. Well-integrated cycles and waves of spermatogenesis ensure that human sperm production is constant at about 1200 sperm per second. Spermatogenesis is an androgen-dependent process that occurs with very high intratesticular testosterone levels. The product of spermatogenesis, the spermatozoa, leave the testis as immotile cells with limited capacity to fertilize oocytes. After epididymal transit, sperm are typically motile and capable of fertilization. During ejaculation, sperm are rapidly transported through the ejaculatory ducts into the urethra from the distal epididymis. The ejaculate itself supports sperm metabolism and motility, serves as an antioxidant, and serves as a barrier to exclude subsequent gamete deposits from gaining access to the egg.

**ANDROGEN DEFICIENCY:
AN EVIDENCE-BASED APPROACH****Introduction**

Testosterone is an essential male hormone. In utero, it serves a paramount role in the proper development of male genital organs. At puberty, it is important for the initiation of spermatogenesis and secondary sexual characteristics. During adulthood, testosterone continues to serve as a predominant circulating androgen, and the male hormonal reproductive axis is a finely controlled system with exquisite control of its biologic effects.

Lessons from androgen deprivation therapy (ADT) for prostate cancer have shown the detrimental effects of androgen deficiency (AD) on overall male health. AD has been associated with mortality in men and a significant decrease in quality of life, from sexual dysfunction to metabolic and musculoskeletal complications (Basaria, 2008). With an aging population, AD in the aging male, known as late-onset hypogonadism (LOH), has become a topic of increasing interest throughout the world.

Gonadal function decline has been recognized as part of normal male aging. It is estimated that testosterone levels in men older than 40 years decrease at a rate of 1% to 2% per year (Bremner et al, 1983). However, unlike female menopause, which is a universal process associated with aging, the exact rate of decline and presenting symptoms are highly variable in men. At the same time, biochemical measurements among assays also produce non-uniform reference ranges because of assay sensitivity variation, making diagnosis difficult (Lazarou et al, 2006).

Heightened awareness of AD has led to the development of many treatment options for LOH. Literature is limited regarding the long-term outcomes of LOH. Despite the wide recognition and adaptation to intervention, debate is ongoing regarding the benefit, and, most importantly, the risks associated with treatment (Connors and Morgentaler, 2013). Although more appears to be known about the aging female, men's health is a rapidly evolving field, and most physicians are actively engaged in bridging the significant knowledge and skill gaps in caring for the aging male population.

Definition

The International Society for the Study of the Aging Male has defined AD syndrome as "a biochemical syndrome associated with advancing age and characterized by a deficiency in serum androgen levels with or without a decreased genomic sensitivity to androgen. It may result in significant alterations in the quality of life and adversely affects the function of multiple organ systems" (Morales and Lunenfeld, 2002). Precise definition of LOH has yet to be established in the literature, despite the fact that Professor Brown-Sequard

first reported it in the nineteenth century (Brinkmann, 2011). Without novel diagnostic markers, neither biochemical nor clinical parameters alone are sufficient for identifying affected individuals.

Epidemiology

According to data from the Organization for Economic Cooperation and Development and Centers for Disease Control and Prevention, U.S. life expectancy was 78.7 years in 2011 (76 for U.S. men and 81 for U.S. women). This represents a 9-year increase from the 1960s, and this increase is consistent with other observed trends in industrialized countries and signifies trends in the aging population around the world. Diseases associated with aging are now integral to the future of medicine, with AD playing an important role in men's health. The true prevalence of AD in the adult male is unknown because of differing definitions in the literature.

The Hypogonadism in Males study was a cohort analysis: Morning serum testosterone levels were obtained from men age 45 years and older who were visiting primary care practices in the United States (Mulligan et al, 2006). Using 300 ng/dL as a threshold for biochemical AD, the overall prevalence was 38.7%. A total of 52.4% of obese and 50% of diabetic men's testosterone values were found to be below the AD threshold. Even though AD symptoms were assessed, only the biochemical definition of AD was used in the study.

Studies that incorporated symptoms along with biochemical testing include Massachusetts Male Aging Study (MMAS) and the European Male Aging Study (EMAS). MMAS was a longitudinal cohort study: Men aged 40 to 70 years with three or more AD signs or symptoms were included (Araujo et al, 2004). Using a cut-off of total testosterone less than 200 ng/dL, the prevalence of AD was 6% and 12.3% at an approximate follow-up of 8.8 years. Researchers reported a crude incidence rate of 12.3 per 1000 person-years, or approximately 481,000 cases of AD in U.S. men aged 40 to 69 years.

In EMAS, the observed prevalence for AD was 2.1% in men aged 40 to 79 years (Wu et al, 2010). Men were categorized as having AD if their serum testosterone was below the threshold of less than 11 nmol/L (approximately 320 ng/dL) and three sexual symptoms were present (erectile dysfunction, decreased libido, and decreased frequency of morning erection). Without accounting for hypogonadal symptoms, the biochemical AD prevalence was 17% in the cohort.

The prevalence of AD associated with systemic disease is higher than for the normal aging process and is well documented (Box 23-1). Since the 1970s, AD has been described in acute illness associated with surgery, stroke, traumatic brain injury, myocardial infarction, respiratory illness, and burns (Kalyani et al, 2007). As many as 90% of men with a total of 15% or more body burns have

been found to be AD (Vogel et al, 1985). Both free and total testosterone values decline rapidly 24 hours after injury and reach a nadir on average at day 11 (Lephart et al, 1987). Mean testosterone level among intensive-care patients has also been suggested to be a predictor for mortality: Surviving patients were shown to have significantly higher testosterone levels than nonsurvivors (Luppa et al, 1991).

Before highly active antiretroviral therapy (HAART), the prevalence of AD ranged from 30% to 50% in men suffering from acquired immunodeficiency syndrome (AIDS)–wasting (Crum et al, 2005). Currently, it still occurs in 20% to 25% of human immunodeficiency virus (HIV)–infected men undergoing HAART. Using a threshold of testosterone concentrations less than 300 ng/dL, AD is associated with AIDS-wasting syndrome and a decline in quality of life.

AD from chronic opioid exposure was first described in 1976 (Cicero et al, 1976). Testosterone levels can reach castration levels (reduced by >85% when compared to controls) within 24 hours after administration of a single opioid (Aloisi et al, 2005). Unlike other opiate-induced side effects, AD persists throughout treatment. In addition to its influence on sexual function, other physiologic changes such as fatigue, muscle wasting, osteoporosis, and changes in pain were also observed (Aloisi et al, 2009).

Testicular dysfunction is present in pretreatment and post-treatment oncologic patients. Approximately one third of patients with Hodgkin disease exhibit oligospermia and up to 70% of men experience abnormal semen parameters (Shekarritz et al, 1995). In testicular cancer, more than 50% of men have oligospermia before treatment (Meirow and Schenker, 1995). Although the exact mechanism of testicular dysfunction is unclear, both central and direct effects on the testis have been suggested (Kalyani et al, 2007).

About two thirds of men undergoing hemodialysis for end-stage renal disease (ESRD) show testosterone values in the AD range (Johansen, 2004). In nondialyzed men with chronic kidney disease, AD was associated with endothelial dysfunction and cardiovascular (CV) events (Yilmaz et al, 2011). In a cohort study of ESRD men, AD is independently associated with inflammation, CV comorbidity, and mortality (Carrero et al, 2011). Renal transplantation appears to reverse the hormonal abnormalities associated with ESRD (Prem et al, 1996). Further long-term study on the efficacy and safety of testosterone therapy (TT) in men with renal dysfunction is still warranted.

Physiology**Transport and Metabolism of Testosterone**

After testosterone is excreted into circulation, the majority of testosterone is bound to plasma proteins. The primary androgen-binding proteins are sex hormone binding globulin (SHBG) and albumin. The majority of testosterone is bound to albumin (54% to 68%); slightly less is bound to SHBG (30% to 44%), and only 0.5% to 3% remains unbound or as free testosterone (Pardridge, 1986). SHBG is produced by the liver and avidly binds to testosterone, rendering it biologically unavailable. Albumin's association with testosterone is much weaker; albumin-bound testosterone and the unbound testosterone compose what is termed *bioavailable testosterone*. These bioavailable testosterone molecules have the ability to enter target organs, bind to the androgen receptor (AR), and initiate protein synthesis.

Testosterone metabolism is important to maintain proper balance between production and to achieve appropriate androgen levels in the target organs. Testosterone metabolism occurs primarily in the liver (Luetjens and Weinbauer, 2012). Extratesticular aromatization results in the conversion of androstenedione to estrone with subsequent reduction to estradiol. The half-life of testosterone in plasma is only about 12 minutes; estrogen influences testosterone's effects by acting either synergistically or antagonistically. Bioavailable estrogen and testosterone are strongly associated with high bone turnover, low bone mineral density, and risk of osteoporotic fractures. The imbalance of the testosterone-to-estrogen ratio is thought to be responsible for the development of impaired glucose tolerance and insulin resistance in the setting of aromatase-deficient men (Maffei et al, 2004).

Testosterone gives rise to 5 α -dihydrotestosterone (DHT) through 5 α -reduction, mainly in the target organs. Although testosterone and DHT both bind to the same intracellular AR, they produce distinct biologic responses. Two isoforms of 5 α -reductase have been identified in humans. Type 1 5 α -reductase has been localized in the nongenital skin, liver, brain, prostate, and testis, whereas type 2 is mainly active in the classical androgen-dependent tissues, such as the epididymis, genitalia, seminal vesicle, testis, and prostate but also in liver, uterus, breast, hair follicles, and placenta (Luetjens and Weinbauer, 2012). DHT is responsible for normal sexual development and virilization in men and when combined with transactivation of AR leads to prostate gene transcription and growth (Penning et al, 2000).

A functional AR is crucial for the optimal action of the androgens. The AR is a ligand-activated transcription factor present in all tissues responsive to testosterone or DHT. The human AR gene was cloned and mapped to Xq11-12 more than 20 years ago (Chang et al, 1988). The N-terminal domain harbors two polymorphic repeats, including a polyglutamine repeat of 9-36 residues and a polyglycine repeat of 10-27 glycine residues, and the length of these repeats affects AR transactivation and sensitivity (Werner et al, 2006). The length of trinucleotide repeats cytosine, adenosine, and guanosine (CAG) has been implicated in various disease processes relating to hyperandrogenicity and hypoandrogenicity. The contribution of CAG repeat polymorphism to prostate cancer has been well described; either to age of onset (Latil et al, 2001) or to the general risk development (Balic et al, 2002). The longer the CAG repeat in the AR gene translates to decreased androgen sensitivity, the earlier the onset of the AD is observed and the more severe the symptoms of AD are (Dejager et al, 2002).

Etiology. AD can be a result of testicular failure (primary hypogonadism), or it can be caused by the disruption at the hypothalamic–pituitary–gonadal (HPG) axis level (secondary hypogonadism). It is important to identify defects in the central level, as it can be a consequence of pituitary pathology, which can be restored by hormonal stimulation in most patients with secondary hypogonadism (Table 23-1). The pathophysiology of these disorders is characterized by alteration of secretion or action of gonadotropin-releasing hormone (GnRH), resulting in impairment

TABLE 23-1 Forms of Hypogonadism

PRIMARY HYPOGONADISM	
DISEASE	CAUSES OF DEFICIENCY
Maldescended or ectopic testis	Failure of testicular descent, 85% idiopathic
Orchitis	Viral or bacterial etiology
Congenital anorchia (bilateral in 1 in 20,000 males, unilateral 4 times as often)	Probably intrauterine torsion
Acquired anorchia	Traumatic, torsion, inflammation, orchiectomy
Secondary testicular dysfunction	Medication, systemic disease, radiotherapy, or toxin exposure
46,XY disorders of sexual development (male pseudohermaphroditism)	Enzymatic defects of steroid biosynthesis
47,XXY syndrome	Nondisjunction in paternal meiosis
Gonadal dysgenesis	Genetic mutations
Leydig cell hypoplasia	Luteinizing hormone receptor mutation
Noonan syndrome	Autosomal dominant congenital disorder

From Dohle GR, Arver S, Bettocchi C, et al. Guidelines on male hypogonadism, <http://www.uroweb.org/gls/pdf/17_Male_Hypogonadism_LR.pdf>; 2013 [accessed 04.11.14].

of pituitary luteinizing hormone (LH) and follicle-stimulating hormone (FSH) secretion (Pitteloud et al, 2010).

As men age, testosterone serum levels progressively decrease (Harman et al, 2001). Despite the recognition of this phenomenon since the nineteenth century, the exact mechanism is yet to be elucidated. Circulating LH concentrations do not decline as men age (Harman and Tsitouras, 1980), suggesting that reduced testosterone results from primary gonadal hypofunction rather than changes at the hypothalamic-pituitary levels.

Reduction in testosterone levels might be caused by a reduced number of Leydig cells or by reduced androgenic activity of the cells. AD is also observed with aging in rodents. In the Brown Norway rat strain, similar hormonal changes were observed with aging, and they were studied extensively as models of aging testis (Chen et al, 1994). The number of Leydig cells per testis has been shown to remain unchanged, suggesting that changes in the steroidogenic machinery of the individual cells and not their reduced number are responsible for the declining serum testosterone concentrations. Furthermore, Leydig cells from aged Brown Norway rats have been shown to produce less cAMP and testosterone in response to LH when compared to young rats (Chen et al, 2002). Consistent with animal studies, the administration of human chorionic gonadotropin (hCG) has been shown to stimulate testosterone production to a lesser extent in older than in younger men (Liu et al, 2005), suggesting reduced responsiveness of Leydig cells to LH. Although serum LH levels do not change significantly with age, age-related changes in LH frequency and amplitude have been reported (Bonavera et al, 1997), and these changes could affect Leydig cell testosterone production.

In the setting of systemic illness, alterations in both HPG axis and testicular function have been demonstrated. HPG axis suppression was observed after acute injury: Significant falls of FSH and LH along with testosterone and estradiol were found in both genders (Woolf et al, 1985; Bonavera et al, 1997). In addition to declining

LH levels, decreased pulsatility of LH release in burn patients has also been found, suggesting another plausible mechanism for central hypogonadism (Semple et al, 1987). The degree of HPG suppression is related to the severity of illness in critically ill patients. Both APACHE (Acute Physiology and Chronic Health Evaluation) score and degree of burns in patients were shown to correlate with degree of AD (Kalyani et al, 2007). Severity of head trauma also correlated with AD, and patients who presented with the lowest Glasgow Coma Scale score displayed the lowest levels of baseline and peak FSH and testosterone (Dimopoulou et al, 2004).

Other illnesses also exhibit suppression of the HPG axis. Central hypogonadism is more common in HIV-positive patients. Malnutrition with acute and chronic illness can cause significant weight loss and can disrupt the HPG axis (Dobs et al, 1996). Cytokines have also been implicated in the AD of HIV-infected men: Interleukin (IL)-1 was shown to inhibit gonadotropin release and LH binding to Leydig cells, and tumor necrosis factor can also affect HPG axis (Mylonakis et al, 2001). Naturally occurring opiates (endorphins) inhibit GnRH, and the direct suppressive effect of chronic opioid exposure on the pituitary and testis was proposed (Blank et al, 1986). Uremia also diminishes the amplitude of pulsatile LH release leading to secondary hypogonadism (Palmer, 1999).

Many mechanisms of testicular injury from systemic illness have been demonstrated. Both the germinal epithelium and Leydig cells of the adult testis are more highly predisposed to cytotoxic damage than the prepubertal testis. In a cohort study of patients undergoing high-dose chemotherapy for a variety of hematologic malignancies, one third of the patients showed evidence of Leydig cell dysfunction and 90% of patients experienced germinal epithelial failure (Howell et al, 1999). Single-dose irradiation as low as 0.1 Gy can cause testicular dysfunction, and doses greater than 0.8 Gy result in azoospermia (Rowley et al, 1974). Factors affecting impairment and recovery of testicular function after cytotoxic therapy include the agent used, the dose received, and the maturation of testis at the time of insult (Pryzant et al, 1993). Testicular atrophy from opportunistic infections was also suggested; nonspecific interstitial inflammation and fibrosis were observed in 32% of AIDS patients during autopsy examination (De Paepe and Waxman, 1989). A serum factor present in uremia also exhibits inhibition of LH receptor resulting in decreased Leydig cell sensitivity to LH (Handelsman and Dong, 1993). In alcoholic liver disease, primary testicular failure resulting from defective morphology of Leydig cells caused by ethanol can occur even before any clinical sign and symptom of AD are present (Gursoy et al, 2004).

Systemic illness can also affect testosterone metabolism and transport. The prevalence of AD in chronic liver disease is unknown. Liver failure and other systemic illnesses are associated with elevated levels of sex hormone-binding globulin (SHBG) in liver failure, leading to the overestimation of bioavailable testosterone. Therefore a direct assay for free testosterone might be used in the initial evaluation of the patient's endocrine status, because AD is a

KEY POINTS: EPIDEMIOLOGY AND PHYSIOLOGY

- The true prevalence of AD in the adult male is unknown as a result of inconsistent definitions used in the literature. Population-based studies suggest the prevalence to be between 2.1% and 38.7%.
- The prevalence of AD in men suffering from systemic diseases is significantly higher than those not evincing these diseases. Physicians caring for these patients need to be aware of the increased prevalence and need to offer appropriate screening.
- AD can be a result of primary testicular failure or can be caused by the disruption at the HPG axis. Testosterone metabolism and transport can also be affected by systemic illnesses.
- A functional AR is critical for the action of androgens. AR polymorphism likely contributes to the clinical symptomatology, treatment response, and adverse reaction to therapy.

significant risk factor for osteoporosis and for spinal fracture, and it is a predictor of mortality in men (Grossmann et al, 2012).

Diagnosis

Diagnosis of AD poses several challenges in men. Clinical signs and symptoms are often nonspecific, and modification by age, comorbid illness, severity and duration of AD, variation in androgen sensitivity, and previous TT can all lead to variable presentation. Multiple questionnaires were developed to screen and quantify the severity of AD in aging men (Table 23-2). Researchers at Saint Louis University first developed the **Androgen Deficiency in Aging Male (ADAM)** in 2000 (Morley et al, 2000). The standard ADAM questionnaire consists of 10 “yes or no” questions concerning symptoms of AD without severity of symptoms. The report initially presented a sensitivity of 88% and specificity of 60% in identifying men with serum biochemical AD as defined by bioavailable free testosterone that was less than 90 ng/dL. However, it was shown to be less specific at 60% in a study of Spanish men older than 50 years of age (Martinez-Jabaloyas et al, 2007). A modification of the original ADAM by quantifying each of the 10 symptoms into a Likert scale of 1 to 5 was shown to improve the questionnaire’s correlation with biochemical AD in a group of men with prostate cancer (Mohamed et al, 2010). The **Aging Male Symptom (AMS)** scale consists of a battery of 17 questions graded on a Likert scale of 1 to 5, which allows one to quantify the degree of improvement in AD symptoms after therapy. However, similar to standard ADAM, AMS lacks specificity. In a study of 1174 men with AD who were undergoing treatment for TT, authors found a sensitivity of 96% but a specificity of only 30% (Moore et al, 2004). The questionnaire from MMAS is mainly a risk questionnaire using a combination of symptom and epidemiologic findings. It was validated against AD as defined by serum total testosterone less than 12.1 nmol/L (Smith et al, 2000), with a sensitivity of 60% and specificity of 59% (Morley et al, 2006). These questionnaires mainly serve as screening tools; their usefulness in diagnosing and evaluating treatment efficacy remains to be determined.

Men with suspicious signs or symptoms or at risk for AD need confirmatory biochemical testing before the diagnosis is made. We do not yet know the exact biochemical threshold serum testosterone concentration below which symptoms of AD and adverse outcomes occur (Table 23-3). Age, target tissue, and androgen sensitivity all can affect threshold of testosterone levels producing various symptoms. The average testosterone threshold corresponding to the lower limit of the normal range for young men, approximately 300 ng/dL (10.4 nmol/L), was shown to be associated with

greater likelihood of experiencing clinical symptoms (Zitzmann et al, 2006).

Serum testosterone levels peak in the morning and vary significantly as a result of circadian and circannual rhythm (Bremner et al, 1983). Most normal ranges for testosterone levels are established using morning blood samples, therefore diagnostic biochemical measurement for AD should be performed in the morning. Even though the effect of circadian rhythm is blunted with aging, a substantial fraction of men older than 65 years who had low serum testosterone levels in the afternoon was shown to have normal testosterone concentrations in the morning (Brambilla et al, 2007). It is important to confirm low testosterone concentrations in men with initial testosterone level less than the biochemical threshold range. In a cohort study of men aged 30 to 79 years, the day-to-day intraindividual variation in the level of testosterone exceeded the approximate 25% difference in half the men (Brambilla et al, 2007). Serum total testosterone concentration represents both protein-bound and unbound testosterone in circulation. Bioavailable testosterone refers to unbound testosterone and albumin-bound testosterone that is readily dissociable. Free or bioavailable testosterone concentrations should be measured when total testosterone levels are at the lower limit

of the normal range or when altered SHBG levels are suspected (Box 23-2). It is also important to assess gonadotropins and prolactin during confirmatory testing to exclude secondary hypogonadism. If abnormality of the HPG axis is suspected, magnetic resonance imaging (MRI) of the central nervous system is indicated.

Total testosterone concentrations can be measured by three methods: radioimmunoassay, immunometric assay, or liquid chromatography tandem mass spectrometry. In most laboratories, automated immunoassays for total testosterone are performed using chemiluminescence detection. A major problem exists when the standard reference range for the adult male does not correspond to values reported by clinical laboratories (Bhasin et al, 2008). There are significant variations among assay techniques and among different laboratories. An external quality-control program by the College of American Pathologists has shown that the interlaboratory variation of a control sample is in a range between 215 and 348 ng/dL (7.5 and 12 nmol/L) with coefficients of variation among laboratories using the same method ranging between 5.1% and 22.7% (Wang et al, 2004). Using liquid chromatography tandem mass spectrometry as the standard, both radioimmunoassay techniques and automated immunoassay techniques performed within the clinically acceptable limits of $\pm 20\%$ of the reference method in more than 60% of the samples at differentiating the eugonadal from the AD male with established reference ranges for the particular laboratory. However, with their lack of precision at low testosterone levels, the tested assays cannot be used to measure testosterone accurately in females or prepubertal subjects.

Equilibrium dialysis is the gold standard for measuring free testosterone; however, it is costly and is often unavailable in local laboratories. Many analog methods are frequently used in place of equilibrium dialysis, but these methods are heavily affected by SHBG levels and are often inaccurate (Rosner et al, 2007). Routine free testosterone testing using analog measurement is not recommended by the American Endocrine Society. Many calculations were developed to estimate free testosterone concentrations from total testosterone, SHBG, and albumen. The calculated free testosterone values are dependent on the quality of total testosterone and SHBG assays. Because calculations are systematically different from equilibrium dialysis measurements, a significant variability exists in the calculated free testosterone estimates (Sartorius et al, 2009).

Diagnosis for AD in men should begin with a general health evaluation to assess for clinical signs, symptoms, systemic illness, and medications that might contribute to transient depression of testosterone levels. Confirmatory biochemical testing should be performed to support any clinically suspected cases. Gonadotropins and prolactin evaluation is crucial to identify alteration of the HPG axis, and an appropriate imaging study should also be performed. Urologists must become familiar with the limitation of the biochemical assays and the reference range of their local laboratory. Health care providers must exercise clinical judgment in selecting appropriate patients for treatment, because no single modality is capable of providing an accurate diagnosis of AD (Fig. 23-1).

KEY POINTS: DIAGNOSIS

- All men suspected of having AD need to undergo confirmatory biochemical testing.
- The exact biochemical threshold testosterone concentration that correlates with symptoms of AD or adverse outcomes has yet to be elucidated.
- The gold-standard biochemical assay for testosterone is often unavailable; physicians need to be familiar with their local laboratory's protocol and the limitations of different methodologies.
- If testosterone levels are below or at the lower limit of the accepted normal values, a repeat confirmatory morning test along with an assessment of the pituitary function are required.
- In men with abnormal gonadotropins (secondary hypogonadism), MRI of the pituitary might be indicated.

Treatment

The goal of AD treatment is to restore physiologic testosterone levels in AD men while alleviating symptomatic AD. Given the nonspecific clinical presentation of AD, physicians must counsel patients on lifestyle modifications in addition to TT. Increased physical activity, reduction of total caloric intake, and tobacco cessation have all been shown to reduce the risk of cardiovascular disease (CVD) and are part of the first-line management of metabolic syndrome based on American Heart Association recommendations (Grundy et al, 2005). Only by combining lifestyle changes with the restoration of androgen balance can the optimal health of the aging male be achieved.

Randomized controlled studies have shown that TT provides several positive improvements in body composition, metabolic control, and psychological and sexual parameters. For a group of elderly men with stable congestive heart failure, those patients receiving long-acting TT in addition to optimal medical therapy experienced improved exercise capacity (peak oxygen consumption), quadriceps isometric strength, insulin sensitivity, and baroreflex sensitivity compared to the placebo-controlled group (Caminiti et al, 2009). In a meta-analysis of randomized placebo-controlled trials, intramuscular (IM) TT was associated with an 8% gain in lumbar bone mineral density score with mixed results on femoral neck bone mineral density (Tracz et al, 2006). Cohort studies on long-acting TT have demonstrated a clear decrease in waist circumference, a significant reduction in trunk adipose composition and body mass index (BMI), and improvement of lipid profile after 1 year of therapy (Saad et al, 2007; Haider et al, 2010). In a multicenter prospective study, AD men receiving long-acting TT showed a significant improvement in the International Index of Erectile Function (IIEF) score for libido, intercourse satisfaction, and overall satisfaction at 6 weeks of therapy (Moon du et al, 2010). Meta-analysis of randomized, placebo-controlled trials showed that TT in patients with borderline biochemical AD was associated with minimal improvement in erectile function (95% confidence interval [CI] 0.03 to 0.65), nonsignificant effect on libido (95% CI -0.01

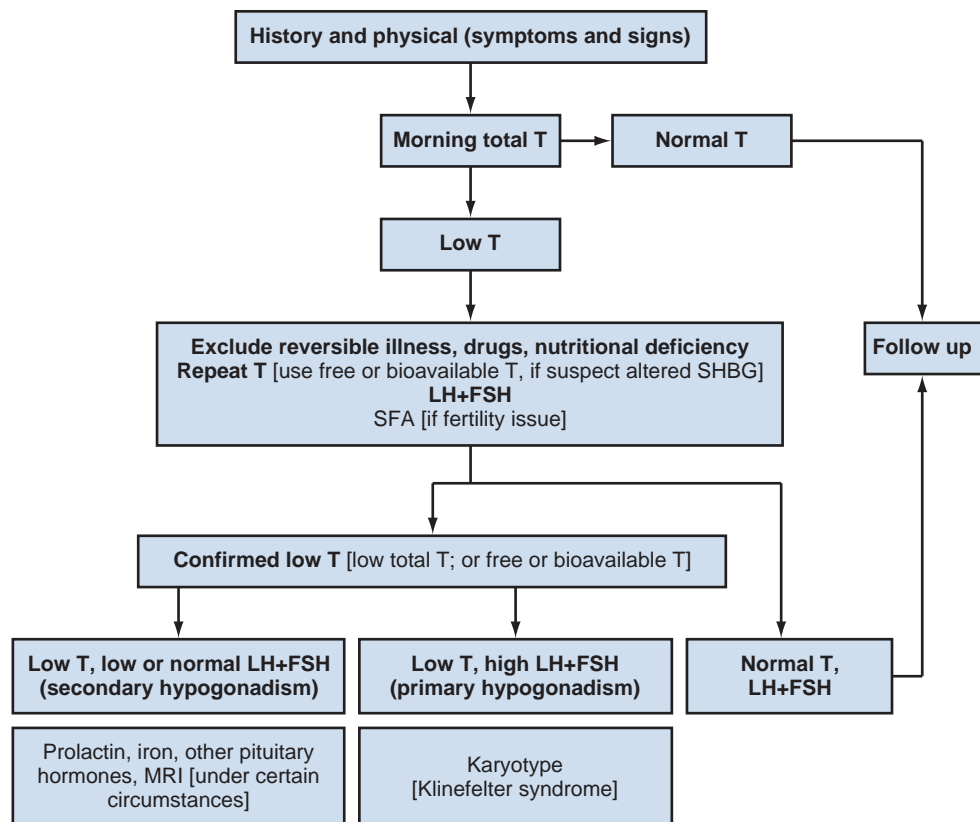

Figure 23-1. Approach for the evaluation for suspected androgen deficiency: endocrine guideline. FSH, follicle-stimulating hormone; LH, luteinizing hormone; MRI, magnetic resonance imaging; SFA, sperm fine-needle aspiration; SHBG, sex hormone binding globulin; T, testosterone. (Modified from Bhasin S, Cunningham GR, Hayes FJ, et al. Testosterone therapy in men with androgen deficiency syndromes: an Endocrine Society clinical practice guideline. *J Clin Endocrinol Metab* 2010;95:2536–59.)

to 0.83), and no effect on overall sexual satisfaction (Bolona et al, 2007). In a randomized, placebo-controlled study of AD men with metabolic syndrome, long-acting TT administration significantly improved depressive symptoms (–2.5 points, Beck depression inventory), AD symptoms (–7.4 points, AMS), and sexual function (+3.1 points, IIEF) after 30 weeks of therapy as compared to the control group (Giltay et al, 2010). In placebo-controlled, randomized trials of aging men, TT failed to show significant improvement in cognitive function (Blackman et al, 2002; Kenny et al, 2004).

Randomized controlled studies also demonstrated the benefit of TT in patients suffering from systemic diseases. In a study of 70 HIV-positive men with symptomatic and biochemical confirmation of AD, biweekly IM TT was shown to improve libido, fatigue, depressive mood, and muscle mass compared to the placebo group (Rabkin et al, 2000). In a small randomized study of asthmatic men receiving long-term glucocorticoid treatment, TT increased bone density of the lumbar spine by 5% compared to no change in the placebo group after 1 year of therapy (Reid et al, 1996). In a double-blind, placebo-controlled trial of men with severe burn (40% to 70% of body surface), patients treated with a testosterone analogue, Oxandrolone, were found to decrease significantly both weight and net nitrogen loss while improving donor-site wound healing compared to the placebo group (Demling and Orgill, 2000).

Administration of native testosterone either orally or parenterally results in absorption by portal circulation and rapid metabolism by the liver, and only a small concentration reaches the systemic circulation (Qoubaitary et al, 2005). Advancement in chemical modification using esterification results in a series of testosterone analogues with improved bioavailability and pharmacokinetics (Corona et al, 2011) (Fig. 23-2).

Figure 23-2. Biochemical structure of testosterone and potential site of modification: chemical structure of testosterone and possible site of structural modification to improve its bioavailability and pharmacokinetics. (Modified from Corona G, Rastrelli G, Forti G, et al. Update in testosterone therapy for men. *J Sex Med* 2011;8:639–54.)

TT is indicated in AD men who are demonstrating a decline in muscle mass and strength, a reduction of bone mineral density, and a decrease in sexual function (Boxes 23-3 and 23-4). TT is safe, and several preparations are available: oral, buccal, transdermal, IM injections, and subcutaneous implantation (Table 23-4 and Box 23-5). TT's goal and aim is to restore biochemical testosterone levels in a range for healthy young men. Physicians need to

be aware of the pharmacology of different TT formulations to avoid undertreatment and overtreatment when both are associated with increased adverse events. The principle of treatment with a short-acting formulation to assess efficacy and side effects before commitment to a long-acting preparation should be followed.

Oral Preparations

Oral alkylated testosterone preparations are associated with **hepatotoxicity**; use is considered obsolete and is no longer recommended. The only oral testosterone formulation available is testosterone undecanoate (TU), and its absorption is via the lymphatics,

bypassing liver metabolism to enable delivery (Seftel, 2007). This formulation is currently not available in the United States. The absorption via lymphatic route is highly dependent on the fat content of food intake: It must be taken with at least 20 mg of fat. Oral TU has a short half-life (approximately 4 hours) and it requires multiple dosing (2 to 3 times daily), resulting in irregular serum

BOX 23-3 Indications for Testosterone Therapy

Delayed puberty (idiopathic, Kallmann syndrome)
Klinefelter syndrome with hypogonadism
Sexual dysfunction with low testosterone
Low bone mass in hypogonadism
Adult men with signs and symptoms of hypogonadism
Hypopituitarism
Testicular dysgenesis with low testosterone

From Dohle GR, Arver S, Bettocchi C, et al. Guidelines on male hypogonadism, <http://www.uroweb.org/gls/pdf/17_Male_Hypogonadism_LR.pdf>; 2013 [accessed 04.11.14].

BOX 23-4 Contraindications for Testosterone Therapy

VERY HIGH RISK OF SERIOUS ADVERSE OUTCOMES

Metastatic prostate cancer
Breast cancer

MODERATE TO HIGH RISK OF ADVERSE OUTCOMES

Unevaluated prostate nodule or induration
Hematocrit greater than 50%
Severe lower urinary tract symptoms associated with benign prostatic hypertrophy (American Urological Association International Prostate Symptom Score >19)
Poorly controlled congestive heart failure
Unevaluated sleep apnea

From Bhasin S, Cunningham GR, Hayes FJ, et al. Testosterone therapy in men with androgen deficiency syndromes: an Endocrine Society clinical practice guideline. J Clin Endocrinol Metab 2010;95:2536–59.

TABLE 23-4 Available Testosterone Therapy Preparations

COMPOUND	DOSAGE	ADVANTAGES	DISADVANTAGES
ORAL AGENTS			
Testosterone undecanoate	120-240 mg, 2-3 times daily	Oral, adjustable dose	Variable testosterone levels and clinical response, must be taken with meals containing at least 20 g of lipids
INTRAMUSCULAR AGENTS			
Testosterone enanthate	200 mg every 1-2 wk	Low cost	Wide fluctuation in testosterone levels, multiple injections, increased risk for polycythemias
Testosterone cypionate	100-200 mg every 1-2 wk		
Testosterone propionate	100 mg every 2 days		
Testosterone undecanoate	750-1000 mg every 10-14 wk	Efficient testosterone normalization, long lasting, improved compliance	Injection site pain, requires injection training
SUBUTANEOUS AGENTS			
Surgical implants	450-700 mg every 4-6 mo	Efficient testosterone normalization, long lasting, improved compliance	Invasive placement, risk of extrusion and site infections
CONTROLLED-RELEASE BUCCAL FORMULATION			
Testosterone buccal	30 mg, twice daily	Oral	Mucosal irritation, twice daily administration
TRANSDERMAL AGENTS			
Testosterone patches	5-10 mg daily	Simple administration, mimics circadian rhythm	Skin irritation, daily administration, hygiene issues
Testosterone gel 1%-2%	40-80 mg daily	Efficient testosterone normalization, flexible doses, simple administration	Skin irritation, daily administration, possible transference during contact
Underarm Testosterone 2% solution	60-120mg daily		
Testosterone gel 1.62%	20.25-81 mg daily

BOX 23-5 Monitoring after Initiation of Testosterone Therapy

1. Evaluate the patient every 3 to 6 months after treatment initiation and then annually to assess symptom response and assess adverse effects.
2. Monitor testosterone level 3 to 6 months after treatment initiation with goal to raise serum testosterone level into the mid-normal range.
 Injectable formulations: Measure serum testosterone level midway between injections.
 Transdermal patch: Assess testosterone level 3 to 12 hours after application.
 Transdermal gels: Assess testosterone level any time after 1 week of treatment.
 Buccal testosterone: Assess testosterone level immediately before or after application.
 Oral agent: Monitor testosterone level 3 to 5 hours after ingestion.
 Testosterone pellets: Measure testosterone levels at the end of the dosing interval.
3. Check hematocrit at baseline, at 3 to 6 months, and then annually.
 If Hct is greater than 54%, stop therapy until Hct decreases to a safe level.
4. Measure bone mineral density of lumbar spine and/or femoral neck after 1 to 2 years of testosterone therapy in men with osteoporosis or low-trauma fracture.
5. Perform DRE and check PSA before initiation of therapy, at 3 to 6 months, and then in accordance with prostate cancer screening guidelines.
6. Additional urologic workup is indicated if there is abnormal DRE, elevation of PSA, worsening lower urinary tract symptoms, or an AUA/IPSS greater than 19.
7. Evaluate formulation-specific adverse effects at each visit.
 Buccal: alterations in taste and examination of gum and oral mucosa for irritation
 Injectable: fluctuations in symptom, fluid retention
 Testosterone patches: irritation at the application site
 Testosterone gels: Advise patient to cover the application sites with clothing, local hygiene before skin-to-skin contact with women or child. Serum testosterone levels are maintained when application site is washed 4 to 6 hours after application.
 Testosterone pellet: Check for signs of infection, fibrosis, or pellet extrusion.

AUA/IPSS, American Urological Association International Prostate Symptom Score; DRE, digital rectal examination; Hct, hematocrit; PSA, prostate-specific antigen.

From Bhasin S, Cunningham GR, Hayes FJ, et al. Testosterone therapy in men with androgen deficiency syndromes: an Endocrine Society clinical practice guideline. *J Clin Endocrinol Metab* 2010;95:2536–59.

testosterone levels throughout the day. Oral TU has the advantages of flexible dosage, self-administration, and immediate decrease in testosterone serum concentrations after cessation of therapy.

Transbuccal Preparation

A sustained-release mucoadhesive system offers an alternative preparation for oral TT. Transbuccal administration allows the absorption of testosterone through oral mucosa bypassing liver metabolism.

Softening and molding the tablet to the shape of the gum work to apply the system, and this tablet must be removed after 12 hours to avoid local irritation. This formulation was shown to restore testosterone to the physiologic levels while demonstrating efficacy similar to other testosterone formulations (Pfeil and Dobs, 2008).

Transdermal Preparations

A variety of transdermal formations is current available. They are normally to be used daily and they deliver consistent serum testosterone levels into the circulation during treatment. Available transdermal testosterone patches are frequently associated with local skin reactions and decreased compliance rate (Seftel, 2007). The patches can be scrotal and nonscrotal, and they can either include or not include enhancers to increase the skin absorption.

Transdermal testosterone gels were first introduced in the United States in 2000. The recommended starting dose is 50 mg/5 g per day, which provides the delivery of approximately 50 mg/day into circulation. The formulations are either 1% or 2% hydroalcoholic testosterone gels capable of continuous delivery of testosterone for 24 hours after a single daily application. **When transdermal gels are applied, testosterone is rapidly absorbed into the stratum corneum, which forms a reservoir and serves as a rate-controlling membrane (Corona et al, 2011).** It is recommended that testosterone gel be applied on intact dry skin over the shoulders, upper arms, axilla, abdomen, or inner thigh area. Dose adjustment might be needed after therapy because skin absorption is variable among men. Testosterone gels show an improved safety profile with a significant decrease in skin adverse reaction compared to the testosterone patch (Wang et al, 2000). **Transference to others during close contact with the skin's surface is a potential adverse event when using testosterone gels.** This risk can be avoided by wearing clothing or by removing the residue of gel on the skin by local hygiene or by showering after the mandatory residence time (2 to 4 hours based on the preparation).

Injectable Preparations

Injectable 17 β -hydroxyl esters are available in oil depot formulation. When administered into the muscle, testosterone is absorbed directly into the bloodstream. The frequency of injections is based on their half-lives. The propionate-testosterone ester is not widely used because of its short-term formulation, requiring 2 or 3 fractionated doses weekly. Cypionate and enanthate-testosterone esters are injected every 2 weeks. **After administration of injectable preparations, supraphysiologic levels of serum testosterone are reached after 24 hours, followed by a gradual decline to AD levels throughout the following 10 to 14 days (Matsumoto, 1994).** The “peak and valley” variation in serum testosterone concentration is often paralleled by variations of well-being and hypogonadal symptom recurrence. It is postulated that the wide fluctuation in testosterone concentrations contributes to the frequent side effects, including polycythemia, requiring dose adaptation, temporary interruption of therapy, and/or phlebotomy.

A longer-lasting injection preparation of TU is available, although not in the United States. It is administered into the gluteal muscle every 12 weeks following a 6-week loading dose. Testosterone is gradually released into systemic circulation at a consistent normal physiologic level while avoiding complications associated with the fluctuation of testosterone levels. Randomized, placebo-controlled studies have validated the clinical efficacy and the ability to maintain therapeutic testosterone levels of injectable TU (Caminiti et al, 2009; Corona et al, 2011).

Subcutaneous Implant Preparation

The testosterone pellet is the only long-acting testosterone formulation approved for the treatment of male AD in the United States, and it is also available as a different preparation in Europe and Australia. The crystalline testosterone pellets are inserted into subcutaneous tissue under local anesthesia, with complications of

infection or pellet extrusion. Serum testosterone reaches supra-physiologic levels approximately 1 month after implantation, with a gradual decline during the following 3 to 6 months (Kelleher et al, 2004). It offers the longest duration of action among the currently available TT preparations with a steady-state delivery in a multi-institution observational study (McCullough et al, 2012). The convenience of long-acting testosterone preparations has the potential to increase patient compliance, although long-term data on the testosterone pellet are still to be determined. In a randomized, crossover study comparing long-acting TT (testosterone pellet vs. injectable TU), patients preferred the injectable formulation despite no difference in clinical efficacy (Fennell et al, 2010). It should be noted that both formulations from the study are not available in the United States.

Any patient undergoing TT requires scheduled follow-up. During the first year of therapy, men should be monitored at 3- to 6-month intervals and at least annually thereafter (see Box 23-5). A complete clinical and andrologic evaluation is mandatory at each visit. Biochemical assessment of hormonal levels along with hematocrit (Hct) and prostate-specific antigen (PSA) are mandatory. Metabolic parameters can also be measured (e.g., lipid profile), whereas liver function testing is no longer required using the available testosterone formulations.

Complications and Controversies

Erythrocytosis

Testosterone appears to stimulate erythropoiesis. ADT and AD are both risk factors for anemia. In men with chronic kidney disease, AD was shown to be associated with reduced responsiveness to erythropoiesis-stimulating agents (Carrero et al, 2012). Despite the known association, the underlying mechanism of testosterone's role in erythropoiesis is poorly understood. One potential mechanism of action of testosterone is by improvement of iron bioavailability. Weekly administration of IM TT appeared to suppress hepcidin, an iron-regulating protein, resulting in erythrocytosis in a dose- and age-dependent manner (Bachman et al, 2010). Elderly men are at increased risk for developing post-treatment erythrocytosis. DHT has also been implicated at testosterone-induced erythrocytosis. In a randomized, placebo-controlled trial, men who received topical DHT experienced asymptomatic increases of Hct despite a decrease in serum testosterone concentrations, requiring the discontinuation of treatment per protocol (Idan et al, 2010).

Erythrocytosis is the most common side effect of TT with variable prevalence based on testosterone formulations; injection therapy is associated with a greater risk of erythrocytosis as compared to topical preparations. Comparing the testosterone patch with IM injections, the rate of erythrocytosis, as defined by Hct greater than 52%, was 15.4% and 43.8%, respectively (Dobs et al, 1999). Increased blood viscosity can aggravate vascular disease in the coronary, cerebrovascular, or peripheral vascular circulation, particularly in the elderly with pre-existing conditions (Jonathan, 2002). Therefore men receiving TT need to be monitored for erythrocytosis and appropriate measures: Dose reduction, withholding of therapy, therapeutic phlebotomy, or blood donation needs to be instituted in appropriate cases.

Benign Prostatic Hyperplasia

Androgen is important for the development of prostate tissue. Chemical or surgical castration results in the reduction of prostate volume. TT poses as a theoretic risk in men with known lower urinary tract symptoms (LUTS) relating to benign prostatic hyperplasia (BPH). Studies have shown a significant increase in prostate volume; measurement by transrectal sonography was associated with TT during the first 6 months of treatment (Pechersky et al, 2002). However, the increase in prostate volume did not translate into worsening LUTS. Multiple studies failed to demonstrate a significant increase in BPH-related voiding symptoms, measured by International Prostate Symptom Score (IPSS), urine

flow rates, postvoid residual volumes or complications, such as urinary retention, in men undergoing TT as compared to placebo-controlled groups (Fernandez-Balsells et al, 2010). Severe LUTS (IPSS >20) is a relative contraindication to TT and patients should consider evaluation and treatment before initiation of therapy. Urinary symptoms should be assessed as part of follow-up monitoring of men undergoing TT.

Prostate Cancer

Advancement in the understanding of androgen's effect on the prostate is the basis of modern ADT for prostate cancer. TT trials have shown a rise in serum PSA levels, which heightened the concern for the development of prostate cancer (Slater and Oliver, 2000). A collaborative analysis of 18 prospective studies showed no association between serum androgen concentrations and risk of prostate cancer (Roddam et al, 2008). Prospective trials on TT did not show an increase in the incidence of prostate cancer or the risk for prostate biopsy compared to placebo groups (Fernandez-Balsells et al, 2010). TT has emerged as a strategy for sexual function rehabilitation following treatment of prostate cancer. Multiple retrospective cohort studies of TT following prostate cancer treatment demonstrated an improvement in the recovery of sexual function without an increased rate of biochemical recurrence compared to matched controls (Pastuszak et al, 2013).

To date, no definitive evidence suggests that TT has a causative role in prostate cancer or that raising serum testosterone levels by exogenous TT increases the risk for prostate cancer. Both prostate cancer and AD are diseases of aging. Therefore a baseline measurement of PSA and a digital rectal examination should be performed during the evaluation of AD. Men with abnormal PSA or abnormal digital rectal examination require appropriate workup and counseling before TT. Careful monitoring of prostate pathology is critical after TT. Prostate biopsy is indicated in the presence of suspected prostate cancer following the established guidelines for eugonadal men.

Lipid Profile. Data on the relation of TT and lipid profile are inconsistent. Supertherapeutic dosage of androgens appears to lower high-density lipoprotein (HDL) levels (Singh et al, 2002). Multiple prospective studies using TT to restore testosterone in physiologic levels have shown either no change or minimal reduction in HDL (Whitsel et al, 2001). Both total cholesterol and low-density lipoprotein (LDL) levels were also unchanged or reduced compared to pretreatment levels. Transdermal preparation appears to have lesser effects on the lipid profile compared to injectable TT. In a double-blinded placebo-controlled study, there was no significant difference in serum lipids and apolipoprotein between healthy men receiving transdermal testosterone and a placebo group during 36 months of treatment (Snyder et al, 2001). Available data suggest that TT within a physiologic range is not associated with detrimental changes of the lipid profile.

Testicular Hypofunction

Testicular size and consistency often diminish after TT. Exogenous testosterone administration leads to excess negative feedback of the HPG axis, which results in suppression of endogenous testosterone production and spermatogenesis. An international multicenter male contraceptive study conducted by the World Health Organization showed that weekly administration of 100 mg IM testosterone enanthate in healthy men resulted in 98% suppression of spermatogenesis to severe oligospermic (<3 million sperm per mL) or azoospermic level (World Health Organization, 1996). Recovery after TT cessation usually occurs in 12 to 15 months, although normal spermatogenesis is not always observed (Gu et al, 2003). Despite existing literature on exogenous testosterone as male contraception, many physicians are unaware of the effect of exogenous testosterone on fertility. A survey of practicing urologists showed that 25% of respondents would use exogenous testosterone for the treatment of male infertility (Ko et al, 2012).

Strategies such as pretreatment sperm cryopreservation or concomitant administration of hCG have been shown to preserve spermatogenesis in men undergoing TT (Hsieh et al, 2013). **Be cautious when initiating TT in men who still desire to preserve fertility.** Physicians need to offer detailed counseling, monitoring of spermatogenesis, and appropriate strategy to preserve fertility.

Other Adverse Reactions

TT was shown to be associated with the development of sleep apnea (Attal and Chanson, 2010). This phenomenon generally occurs in men undergoing high-dosage TT with other identifiable risk factors for sleep apnea. Upper airway anatomy is unaffected by TT, suggesting a potential central mechanism of altered breathing during sleep rather than anatomical obstruction.

Dermatologic reactions are more common with transdermal patches (up to 66%) than with gel preparations (approximately 5%) (Wang et al, 2000). IM injections can cause local pain, ecchymosis, erythema, swelling, hematoma, abscess, or furuncles (von Eckardstein and Nieschlag, 2002). Acne, oily skin, changes in body hair, and flushing have also been observed but are generally well tolerated.

Fluid retention is uncommon and is generally mild. However, caution is needed when initiating TT in men with congestive heart failure or renal insufficiency.

Gynecomastia is a rare complication after TT. It is related to increased serum estradiol levels from aromatization of testosterone and is often managed by dose adjustment of TT.

Testosterone Therapy for Erectile Dysfunction

Erectile dysfunction (ED) has emerged as an important independent risk factor for CVD, and sexual dysfunction is the most specific symptom of LOH (Isidori et al, 2014). **Population-based studies have shown that the prevalence of AD in men experiencing ED ranges from 23% to 47% (Kohler et al, 2008). The association between ADT and sexual dysfunction is well documented but the role of TT as a monotherapy for ED is less clear.**

Testosterone is responsible for normal genital development, and the literature supports its role in erectile physiology. In the central nervous system, testosterone was shown to stimulate the release of excitatory neurotransmitters such as dopamine, oxytocin, and nitric oxide, which control sexual dimorphic development and mating behavior (Hull et al, 1999). Peripherally, testosterone modulates multiple components involved in erectile function: structure, function, and innervation of smooth muscle cells, endothelial function of penile vessels, and fibroelastic properties of the corpus cavernosum (Isidori et al, 2014). Unfortunately many available data derived from animal castration models, which are very different from AD in men, generate uncertainty, further complicated by the limited available human data.

Combination therapy with phosphodiesterase type 5 inhibitors (PDE5-I) and TT is a highly debated topic. PDE5-I monotherapy is effective at improving erection but is often inadequate in addressing other domains of sexual dysfunction, such as decreased libido, for the AD men. The concept of salvage therapy for nonresponders of PDE5-I was examined in a multicenter, double-blind, placebo-controlled study of 173 men (Buvat et al, 2011). Administration of topical TT resulted in additional beneficial effect only in AD men with total testosterone below the threshold of 10.4 nmol/L (300 ng/dL). The concept of combination therapy was further tested in a large randomized trial to address whether TT includes any additional benefit in AD men whose erectile function is already maximized by a PDE5-I (Spitzer et al, 2012). The study definitively confirmed that TT does not provide additional benefit when erectile function is already restored by PDE5-I. However, the study was not powered to assess the role of salvage therapy, because the overall number of PDE5-I failures was low.

In young men with symptomatic AD, TT should be the first-line treatment with high likelihood of improvement in all domains of sexual function, and PDE5-I can be added if necessary. In elderly

men with ED, PDE5-I should be first-line therapy with optimization of comorbid conditions. In the case of nonresponders, TT should be reserved only in men with biochemical confirmation of AD. Available evidence shows that there are no major safety concerns with combination therapy.

KEY POINTS: TESTOSTERONE THERAPY FOR ERECTILE DYSFUNCTION

- ED along with sexual dysfunction is the most specific predictor of AD.
- Testosterone acts peripherally to modulate multiple components responsible for normal erection.
- When erection is restored by PDE5-I, the addition of TT does not result in further benefit of erectile function.
- For ED refractory to PDE5-I, TT has the potential to improve the efficacy of therapy only in men with biochemical AD (<300 ng/dL).

CARDIOVASCULAR DISEASE AND TESTOSTERONE

CVD is the leading cause of death in most developed countries, with an estimated 17.3 million deaths worldwide per year (Laslett et al, 2012). The lifetime risk of coronary heart disease (CAD) at age 40 is one in two for men and one in three for women (Lloyd-Jones et al, 2004). Although mortality has decreased considerably in recent years, CVD and its complications remain highly prevalent and are significant burdens to the health system (Smolina et al, 2012). The American Heart Association projected that costs of CVD care would triple from \$272.5 billion in 2010 to an estimated \$818.1 billion in 2030 (Laslett et al, 2012). Men are at greater risk for CVD than premenopausal women, suggesting a possible influence of sex hormones (Yang and Reckelhoff, 2011).

Both CVD and AD are diseases of aging; they share many risk factors such as age, obesity, diabetes, alcohol consumption, and chronic diseases. **The association between AD and CVD has become evident in observational studies (Araujo et al, 2011). ADT is associated with an increased risk for CV events in patients with prostate cancer (Levine et al, 2010).** Prospective studies demonstrated that ADT increases CVD by affecting various risk factors: increased body weight, decreased insulin sensitivity, altered lipid profile, and increased fat mass. Two population-based studies reported that ADT is associated significantly with CAD and sudden cardiac death or life-threatening arrhythmia (Saigal et al, 2007). Data from the Cancer of the Prostate Strategic Urologic Research Endeavor also showed a significantly increased risk of CV death in men who underwent radical prostatectomy and received ADT compared with those undergoing surgery alone (Tsai et al, 2007). Endogenous testosterone has been suggested as CV-protective or as a secondary risk predictor of other processes, although the mechanism is still unclear.

Men with LOH commonly exhibit coexisting CVD risk factors; the safety of TT is often questioned, given the known adverse reaction of polycythemia. In 2004, the Institute of Medicine reviewed the evidence on TT and concluded that "there is not clear evidence of benefit for any of the health outcomes examined" (Xu et al, 2013). A randomized, placebo-controlled study on TT in elderly men with limitations in mobility was discontinued early because of an increase in CV-related events in the treatment arm despite showing an improvement in musculoskeletal parameters (Basaria et al, 2010). The generalizability of the results was often questioned, however, because the study population was elderly men (mean age of 74 years) with serious chronic illnesses. The number of CV adverse events was small and the trial was not originally designed to analyze CV outcomes. Meta-analysis of randomized studies on the adverse events associated with TT yielded mixed results on CV events and mortality (Fernandez-Balsells et al, 2010; Xu et al, 2013).

A retrospective study of 8709 male veterans showed a 29% increased risk of CV events in men undergoing TT (Vigen et al, 2013). However, the study was criticized for many flaws: improper patient exclusion, unbalanced comparison, and unusual complexity of statistical analysis. Another cohort study using a health care database (Truven Health MarketScan) suggested the risk of myocardial infarction doubled within 90 days after initiation of TT (Finkle et al, 2014). Researchers used prescription claim information, which does not accurately reflect initiation of TT when known patient compliance issues are considered. Additional statistical modeling was applied to the weighted data. Definitive assessment of CV risk associated with TT must await an ongoing large randomized, controlled trial.

Coronary Artery Disease

Traditionally, AD is not considered a risk factor for CAD. An earlier longitudinal case control study reported no significant difference in testosterone between low-risk men who developed CAD and those who did not (Heller et al, 1983). A growing body of evidence suggests a link between low endogenous testosterone levels and CAD. Several studies have demonstrated that patients with CAD as diagnosed by coronary angiography have lower levels of testosterone compared to control subjects (Chute et al, 1987; Sieminska et al, 2003; Cao et al, 2010). In addition to total testosterone, a significantly lower level of bioavailable testosterone was also found in patients with catheterization-proven CAD (Rosano et al, 2007).

In addition, the degree of AD has been reported as having an inverse relationship to the severity of CAD. Epidemiologic evidence reported a fivefold decrease in the risk of severe atherosclerotic CAD between the lowest and the highest quartiles of total testosterone (Chute et al, 1987). Four small studies have demonstrated independently that in men with CAD, lower levels of endogenous testosterone are associated with more severe CAD (Phillips et al, 1994; Rosano et al, 2007; Hu et al, 2011; Li et al, 2012). This correlation between low testosterone and CAD severity has also been demonstrated in both men and postmenopausal women with CAD (Phillips et al, 1997; Kaczmarek et al, 2003). Men with myocardial infarctions and ischemia have been reported as having lower testosterone and an increased estradiol-to-testosterone ratio when compared to controls (Sewdarsen et al, 1986; Lichtenstein et al, 1987).

Several population-based studies examined the association between mortality secondary to CVD and levels of total testosterone. Although some researchers found significantly greater CV mortality associated with lower testosterone concentrations, others did not (Oskui et al, 2013). A meta-analysis showed a trend toward increased CV mortality associated with lower levels of total testosterone, but statistical significance was not reached (Araujo et al, 2011). An analysis of 2416 Swedish men demonstrated that levels of endogenous total testosterone were significantly inversely associated with risk of adverse CV events (Ohlsson et al, 2011). Men in the fourth quartile of total testosterone showed significant improvement in event-free survival for both major adverse CAD events. Several studies also analyzed the association between bioavailable testosterone and CV mortality, and all indicated that a higher risk of CV mortality was associated with lower levels of bioavailable testosterone (Laughlin et al, 2008; Malkin et al, 2010; Menke et al, 2010).

Cerebral Vascular Disease

AD has also been implicated in the development of cerebral vascular disease. Low levels of total testosterone and bioavailable testosterone have been reported as predictive of an increased incidence of cerebral vascular accidents or transient ischemic attack, even after adjusting for conventional risk factors for cerebral vascular disease (Yeap et al, 2009). Multiple studies have demonstrated that low testosterone concentration is associated with increased carotid intimal-media thickness (IMT), which serves as a measure of cerebrovascular atherosclerosis (De Pergola et al, 2003; Fukui

et al, 2003; van den Beld et al, 2003). Several population-based studies reported an inverse association between total testosterone levels and carotid artery IMT that was present after excluding men with cerebral vascular disease; this relationship, however, was not independent of BMI (Svartberg et al, 2006; Debing et al, 2008). Similarly, a cross-sectional analysis of the Tromso cohort demonstrated an inverse association between testosterone levels and total carotid plaque area (Vikan et al, 2009). In studies without association with total testosterone, low levels of bioavailable testosterone were associated with carotid artery IMT after adjusting for age, BMI, and known cerebral vascular disease risk factors (Tsujimura et al, 2012). The association between testosterone and cerebral vascular disease appeared to be gender specific. No association was observed for free testosterone or total testosterone with carotid IMT in young to middle-aged women (Calderon-Margalit et al, 2010) or with progression of carotid IMT and adventitial diameter in perimenopausal women (El Khoudary et al, 2012).

Proposed Mechanism of Testosterone's Action on the Cardiovascular System

Endothelial Dysfunction

Endothelial dysfunction is the first step in the formation of atherosclerotic lesions. Testosterone has been demonstrated as having a protective effect on endothelial function (Fu et al, 2008). Testosterone has been inversely correlated with vascular cell adhesion molecule-1, which is produced by endothelial cells and is upregulated when endothelial cells undergo inflammatory and malignant stimulation. Investigators reported that hypogonadal men exhibited lower levels of endothelial progenitor cells, which are important in endothelial regeneration, and higher levels of an osteocalcin-positive subpopulation of endothelial progenitor cells, which are highly correlated with atherosclerosis progression, compared to eugonadal men (Foresta et al, 2010). Finally, testosterone has been shown to reduce significantly endoplasmic reticulum stress and superoxide generation in human umbilical vein endothelial cells, both of which have been implicated in atherosclerosis; however, when combined with aromatase inhibitors, the protective effect of testosterone was lost, suggesting an estradiol-mediated mechanism (Haas et al, 2012).

The antianginal and anti-ischemic effects of TT have been recognized since the late 1930s (Oskui et al, 2013). TT in AD men suffering from CAD has proven effective in increasing time to 1-mm ST-segment depression with an exercise stress test (Rosano et al, 1999; English et al, 2000). Although testosterone's vasodilatory effects are well recognized, the exact mechanism of action has yet to be elucidated. Testosterone has been reported to induce endothelium-independent relaxation of numerous vascular beds including human internal mammary arteries and radial arteries (Yildiz et al, 2005b). Both in vivo animal models and in vitro models provided evidence that testosterone induces coronary vasodilation by modulating the activity of ion channels. This direct relaxation response to testosterone has been attributed to conduction of non-adenosine triphosphate sensitive potassium channel (Yue et al, 1995), adenosine triphosphate-sensitive potassium channel (Seyrek et al, 2007), and large conductance calcium-activated potassium channel opening action (Yildiz et al, 2005a). Testosterone has also been reported to induce vasodilation by reducing calcium influx into vascular smooth muscle by acting as a selective and potent inhibitor of L-type calcium channels at physiologic levels and as an inhibitor of testosterone-type channels at supraphysiologic levels (Scrugg et al, 2004).

Contrarily, other studies have suggested an endothelium-dependent mediated mechanism behind testosterone's vasodilatory effect (Ong et al, 2000; Kang et al, 2002). Both acute and long-term administration of testosterone in men with CAD have been shown to increase brachial artery flow-mediated reactivity, which induces shear stress release of nitric oxide and subsequently leads to vasodilation. This relation has also been demonstrated in postmenopausal women (Montalcini et al, 2007).

Arterial wall stiffness is an independent predictor of CVD risk. Low testosterone levels have been associated with endothelial dysfunction (Laurent et al, 2006). This inverse relationship has been demonstrated using both pulse pressure and pulse wave velocity as reflections of arterial wall stiffness (Fukui et al, 2007; Corona et al, 2009). Interestingly, the association between testosterone and CVD mortality was lost in male hemodialysis patients after adjusting for pulse wave velocity, suggesting that endothelial dysfunction may be a possible explanation of testosterone's inverse association with CVD (Kyriazis et al, 2011). Contrarily, long-term (8-week) administration of testosterone increased myocardial perfusion in unobstructed coronary arteries and decreased radial and aortic augmentation indexes, indicating decreased arterial wall stiffness; however, no effect was observed on global perfusion or on endothelial function (Webb et al, 2008).

Inflammation

Atherosclerosis is mediated by an ongoing inflammatory response, which is induced by cytokines and other inflammatory markers. Cytokines cause cellular and local arterial wall inflammation and may lead to vascular smooth muscle apoptosis, degradation of the fibrin cap, and plaque rupture, thereby leading to platelet adhesion, thrombus formation, and ultimately angina or myocardial infarction (Malkin et al, 2003). An elevation in inflammatory markers or cytokines has been identified to be predictive of outcomes in patients with CVD (Libby et al, 2002). In a cross-sectional study, inflammatory markers, macrophage inflammatory protein 1- α , 1- β , and tumor necrosis factor- α , have been negatively associated with total testosterone levels in young healthy men, suggesting a low-grade inflammatory state (Bobjer et al, 2013).

TT was reported to suppress the expression of high-sensitivity C-reactive protein and IL-6 in patients who underwent coronary artery stent implantation, leading to the hypothesis that testosterone's anti-inflammatory property could potentially attenuate major CV events (Guler et al, 2006). In a randomized, placebo-controlled, crossover study of AD men, TT reduced levels of proinflammatory cytokines tumor necrosis factor- α and IL-1 β while suppressing levels of cytokine IL-10 (Malkin et al, 2004). However, the inverse relationship between cytokines and testosterone was not identified in AD men with congestive heart failure and in diabetic males compared to eugonadal controls (Pugh et al, 2005; Hernandez-Mijares et al, 2010).

Coagulation

The effect of testosterone on clotting factors including fibrinogen and plasminogen activator inhibitor-1 (PAI-1) has been studied previously. Fibrinogen is a known risk factor for CVD as well as an inflammatory biomarker (Danesh et al, 2005); it increases CVD risk through its effects on atherogenesis, thrombogenesis, and ischemia by the mechanism of increasing plasma and blood viscosity (Kaptoge et al, 2007). It was shown that endogenous testosterone levels were negatively correlated with fibrinogen (Phillips et al, 1994). In a study comparing patients with prostate cancer on ADT to healthy controls, patients on ADT presented with elevated levels of fibrinogen (Ziara et al, 2013). In addition to fibrinogen, PAI-1, another risk factor for ischemic heart disease, was also negatively correlated with endogenous testosterone levels (Yang et al, 1993; Phillips et al, 1994).

Contrarily, a double-blinded, randomized placebo-controlled trial of testosterone supplementation in men with chronic stable angina demonstrated no changes in fibrinogen or PAI-1, suggesting that testosterone supplementation does not affect blood coagulation status (Smith et al, 2005). Moreover, a study comparing chemically or surgically castrated males to eugonadal controls showed that castrated men had less platelet thromboxane A₂ (TXA₂) receptors, suggesting that the inhibition of testosterone production may attenuate platelet aggregation responses (Ajayi and Halushka, 2005).

KEY POINTS: CARDIOVASCULAR DISEASE AND TESTOSTERONE

- Increased awareness has been dedicated to the interplay between testosterone and various aspects of CV health. Existing literature suggests that lower levels of endogenous testosterone are associated with higher rates of all-cause and CV mortality.
- Negative correlation has been demonstrated among endogenous testosterone and severity of CAD, congestive failure, and IMT of the vasculature (Oskui et al, 2013).
- Normal testosterone levels play an important role in maintaining CV health.
- Exogenous TT in men with AD improves myocardial ischemia, exercise capacity, and CV risk factors.
- Current available guidelines do not recommend offering AD screening to patients with heart disease, nor do they recommend supplementing TT to improve outcome.
- Results from the Effects of Testosterone Replacement on Atherosclerosis Progressions in Older Men with Low Testosterone Levels trial have the potential to clarify any long-term adverse consequences and the role of exogenous testosterone in the survival of patients with heart disease.

METABOLIC SYNDROME AND UROLOGIC DISEASES

Introduction

Metabolic syndrome (MetS) is a constellation of clinical factors—including obesity, insulin resistance, hypertension (HTN), and abnormal serum lipid concentrations—associated with an increased risk of incident CVD and diabetes mellitus (DM). Other terms applied to this cluster include the obesity dyslipidemia syndrome, syndrome X, and the deadly quartet. The global prevalence and incidence of MetS have increased substantially since the mid-2000s, particularly in the developed world.

Epidemiologic studies have shown strong associations of MetS and its individual components with increased risks of developing a host of benign and malignant urologic diseases. These observations show novel pathways in the etiology of urologic diseases, underscore the links of urologic conditions with overall health, and suggest new interventions for their prevention and treatment.

These data also have promoted the idea of “men's health,” which, broadly speaking, represents the integration of male urologic care with the prevention and treatment of systemic CVD. However, the concept of men's health is an evolving paradigm with no clearly defined clinical parameters. In the absence of robust randomized clinical trial data and evidence-based guidelines, there are currently few, if any, clearly defined roles for the evaluation or treatment of MetS in the practical management of urology patients.

Definition and Epidemiology

Disagreement exists about the exact diagnostic criteria of MetS. At least five separate organizations have issued definitions, all of which contain the same five basic components (Table 23-5).

The National Cholesterol Education Program (Adult Treatment Panel [ATP] III) issued guidelines in 2001, which the American Heart Association/National Heart, Lung, and Blood Institute updated in 2005. This statement, one of the most commonly used, currently defines MetS as a condition in which at least three of the following factors are present:

- **Abdominal obesity**

Defined as a waist circumference greater than or equal to 88 cm in women and greater than or equal to 102 cm in men

TABLE 23-5 Metabolic Syndrome Definitions

	WHO (1998)	EGIR (1999)	AACE (2003)	IDF (2005)	NCEP ATP III (2005 REVISION)
Required component	IR (IGT, IFG, T2DM, or additional evidence of IR)	Hyperinsulinemia* (plasma insulin >75th percentile)	IR (IGT or IFG)	CO (WC)†	None
Criteria	Required component and $\geq 2/5$ below	Required component and $\geq 2/4$ below	Required component and any below, based on clinical judgment	Required component and $\geq 2/4$ below	$\geq 3/5$ below
Obesity	WHR >0.9 (M), >0.85 (F), or BMI >30 kg/m ²	WC ≥ 94 cm (M), ≥ 80 cm (F)	BMI ≥ 25 kg/m ²	—	WC >102 cm (M), >88 cm (F)
Hyperglycemia (mg/dL)	+	+	+	Fasting glucose ≥ 100	Fasting glucose ≥ 100 or Rx
Dyslipidemia (mg/dL)	TG ≥ 150 or HDL-C <35 (M), <39 (F)	TG ≥ 150 or HDL-C <39	TG ≥ 150 and HDL-C <40 (M), <50 (F)	TG ≥ 150 or Rx HDL <40 (M), <50 (F), or Rx	TG ≥ 150 or Rx HDL <40 (M), 50 (F), or Rx
Hypertension (mm Hg)	>140/90	>140/90 or Rx	>130/85	>130 (S), >85 (D) or Rx	>130 (S), >85 (D) or Rx
Other criteria	Microalbuminuria‡	—	Other features of IR§	—	—

*In patients without T2DM.

†Values are population dependent.

‡Urinary albumin excretion of 20 µg/min or albumin-to-creatinine ratio of greater than or equal to 30 mg/g.

§This includes family history of T2DM, polycystic ovary syndrome, sedentary lifestyle, advancing age, and ethnic groups susceptible to T2DM.

+, criteria fulfilled with required component; AACE, American Association of Clinical Endocrinologists; BMI, body mass index; CO, central obesity; D, diastolic; EGIR, European Group for the Study of Insulin Resistance; F, female; HDL, high-density lipoprotein; IDF, International Diabetes Foundation; IFG, impaired fasting glucose; IGT, impaired glucose tolerance; IR, insulin resistance; M, male; NCEP ATP III, National Cholesterol Education Program Adult Treatment Panel III; Rx, pharmacologic intervention for that criterion; S, systolic; T2DM, type 2 diabetes mellitus; TG, triglycerides; WC, waist circumference; WHO, World Health Organization; WHR, waist-to-hip ratio.

- **Elevated blood glucose**
Fasting plasma glucose greater than or equal to 100 mg/dL or drug treatment for elevated blood glucose
- **Elevated blood pressure**
Blood pressure greater than or equal to 130/85 mm Hg or drug treatment for elevated blood pressure
- **Elevated triglycerides**
Serum triglycerides greater than or equal to 150 mg/dL or drug treatment for elevated triglycerides
- **Decreased HDL cholesterol**
Serum HDL cholesterol less than 50 mg/dL in women and less than 40 mg/dL in men or drug treatment for decreased HDL cholesterol

Epidemiology of Metabolic Syndrome

MetS is common, and there is evidence that its prevalence is substantially increasing. Among 8814 U.S. adults participating in the third National Health and Nutrition Examination Survey (NHANES III, 1988 to 1994) the overall prevalence of MetS as defined by the 2001 ATP III criteria was 22%. Prevalence increased steadily with age; Mexican-Americans had the highest age-adjusted prevalence (31.9%). The age-adjusted prevalence for men (24.0%) was similar to women (23.4%) (Ford et al, 2002). An updated analysis among 1677 participants from NHANES 1999 to 2000 demonstrated that the overall prevalence had increased to 26.7% ($P = .043$), a trend driven primarily by a 23.5% increase in prevalence among women (Ford et al, 2004).

Similarly, among 3323 adult participants in the Framingham Heart Study, the baseline prevalence of MetS as defined by the 2005 revised ATP III criteria was 26.8% in men and 16.6% in women. After 8 years of follow-up, there was an age-adjusted 56% increase in prevalence among men and a 47% increase among women (Wilson et al, 2005).

Metabolic Syndrome and Clinical Urology

Although an emerging body of knowledge links MetS to the development of urologic diseases, and familiarity with these concepts is important, practical applications of these data to urologic practice are currently limited. At least two clinical issues remain unresolved with respect to MetS and the care of the urology patient.

First, because the management of MetS-related conditions primarily rests with cardiologists, endocrinologists, and primary care physicians, how urologists should approach urologic diseases in the context of MetS is currently unclear. Pathophysiologic links of MetS with urologic diseases, and a small number of clinical trials, imply that treating systemic manifestations of MetS will mitigate their effects on urologic conditions. Yet weight loss, lipid control, and other medical interventions do not typically fall within the purview of urologic practice; and without substantial changes in current care delivery paradigms, it is unlikely that urologists will oversee these therapies independent of other health care providers.

Second, because ED and male LUTS are potential markers for occult CVD (Thompson et al, 2005), some investigators have proposed that urologists routinely screen for CVD. This endeavor, too, is one that urologists do not normally pursue. Moreover, CVD screening is a discipline for which most urologists typically lack formal training, and it is therefore fraught with as-yet-unanswered practical, medical, and medicolegal questions.

Metabolic Syndrome, Benign Prostatic Enlargement, and Male Lower Urinary Tract Symptoms

MetS and its individual components have been associated with increased risks of benign prostatic enlargement (BPE) (formerly known as benign prostatic hyperplasia [BPH]) and

male LUTS. Definitions of BPE in the literature are heterogeneous and include radiographically determined prostate enlargement, decreased urinary flow rates, history of noncancer prostate surgery, physician diagnosis, and urinary symptoms.

LUTS describes a distinct phenotype of a group of disorders affecting the prostate and bladder that share a common clinical manifestation. In its evidenced-based report, the International Consultation on Urological Diseases (2012) used the term "LUTS" to classify the diagnosis, treatment, and study of these conditions. LUTS has also become the preferred term for studying urinary symptoms in populations. Most studies use the IPSS or the American Urological Association Symptom Index (AUASI) to quantify the severity of symptoms; older studies focused on specific symptoms, including nocturia and frequency.

Metabolic Syndrome and Cardiovascular Disease

A systematic review and meta-analysis of 8 studies involving more than 5400 men observed significant direct associations of a diagnosis of MetS with increased prostate volume (Gacci et al, 2015).

Other studies have shown that men with cardiac disease or who are receiving treatment for cardiac disease (and thus have a high likelihood of having at least one component of MetS) are at significantly increased risks of physician-diagnosed BPE and LUTS (De Nunzio et al, 2012).

Correlation between Metabolic Syndrome and Prostatic Diseases

Obesity

Increased adiposity is associated with increased ultrasound- and MRI-determined prostate volume as measured by body weight, BMI, and waist circumference. In the Baltimore Longitudinal Study of Aging (BLSA) cohort, each 1 kg/m² increase in BMI corresponded to a 0.41 mL increase in prostate volume, and obese (BMI ≥35 kg/m²) participants had a 3.5-fold increased risk of prostate enlargement compared to nonobese (BMI <25 kg/m²) participants (*P* trend = .06) (Parsons et al, 2006; Raheem and Parsons, 2014).

Obesity has been associated with increased risks of symptomatic BPE and LUTS in several different populations, including the U.S. Health Professionals Follow-up Study (*n* = 26,000), a study group in China (*n* = 500), a 7-year prospective analysis of the U.S. Prostate Cancer Prevention Trial (PCPT) (*n* = 4770), NHANES III (*n* = 2800), the second Nord-Trøndelag Health Study (HUNT-2) (*n* = 21,700), and the Prostate Study Group of the Austrian Society of Urology (*n* = 1500). Other studies have shown that obesity increases the risks of BPE surgery, initiation of BPE medical therapy, and LUTS (Raheem and Parsons, 2014).

Obesity also attenuates the efficacy of the 5 α -reductase inhibitors (5ARI) finasteride and dutasteride, which decrease serum concentrations of DHT, prevent clinical progression of BPE and LUTS, and prevent incident-symptomatic BPE. An analysis of the PCPT showed that obesity diminished the efficacy of finasteride for preventing symptomatic BPE. Similarly, a secondary analysis of the Reduction by Dutasteride of Prostate Cancer Events (REDUCE) trial concluded that obesity enhanced prostate volume growth and weakened the magnitude of prostate volume reduction by dutasteride. These observations likely highlight a balance between 5ARI-driven prostate volume reduction and obesity-driven prostate volume growth (Parsons, 2010, 2011; Raheem and Parsons, 2014).

Diabetes and Disruptions in Glucose Homeostasis

Higher serum concentrations of insulin-like growth factor-1 and insulin-like growth factor binding protein-3 were consistently associated with increased risks of BPE diagnosis and BPE surgery. DM, increased serum insulin, and elevated fasting plasma glucose have been associated with increased prostate volume and prostate enlargement, clinical diagnosis of BPE, BPE surgery, and LUTS in many different cohorts cumulatively involving tens of

thousands of men (Sarma et al, 2009; Parsons, 2010, 2011; Raheem and Parsons, 2014).

Diabetes and Disruptions in Glucose Homeostasis: The Epidemiology of Diabetes Interventions and Complications Study

The Epidemiology of Diabetes Interventions and Complications (UroEDIC) follow-up study of the Diabetes Control and Complications Trial (DCCT) was a post hoc analysis of 591 men enrolled in a randomized clinical trial comparing intensive to conventional glycemic control in type 1 DM (Van Den Eeden et al, 2009). The aim was to determine whether intensive glycemic control reduces LUTS severity in men with type 1 DM. Intensive treatment consisted of insulin administered three or more times daily by injection or by infusion pump coupled with rigorous monitoring of blood glucose levels. No associations were observed between LUTS, as measured by the AUASI, and intensive glycemic control. However, because these men were younger (mean age 45 years) and had type 1 rather than type 2 DM, these data may not apply to the broader population of older diabetic men with LUTS.

Elevated Blood Pressure

Associations of HTN with BPE and LUTS remain unclear. There have been at least six studies among men with HTN, three of which observed an increased risk of LUTS, one of which noted an increased risk of BPE surgery, and two of which observed no risk.

Elevated Triglycerides and Decreased High-Density Lipoprotein

Studies of BPE and LUTS with serum triglycerides and HDL are also conflicting. There have been at least six studies, including three showing positive and three showing null associations (Hammarsten et al, 1998; Zucchetto et al, 2005; Gupta et al, 2006; Lekili et al, 2006; Nandeeshia et al, 2006; Parsons et al, 2008; Parsons, 2011).

Metabolic Syndrome and Urinary Incontinence

MetS and some of its features, primarily obesity, were linked to a higher risk of urinary incontinence in women.

Metabolic Syndrome

One study of 400 women in Turkey observed an increased, albeit unadjusted, risk of stress urinary incontinence (SUI) in those with MetS compared to those without it in both the pre- and postmenopausal groups (*P* = .001 and *P* < .001, respectively) (Octuntemur et al, 2014).

Obesity

Multiple studies have noted strong associations of obesity with urinary incontinence in women across different populations. In a cross-sectional analysis of Taiwanese women, those who were obese (BMI >27 kg/m²) had a more than threefold (odds ratio [OR] 3.38, 95% CI 1.94 to 6.98, *P* < .001) increased adjusted risk of incontinence (stress, urge, or mixed) compared to those of normal weight (BMI ≤24 kg/m²) (Tsai and Liu, 2009).

In a study of more than 19,000 Chinese women, waist circumference greater than or equal to 80 cm was associated with an increased adjusted risk of SUI (OR 1.38, 95% CI 1.25 to 1.52) (Zhu et al, 2009); in another study by the same investigators that measured BMI, overweight (OR 1.31, 95% CI 1.12 to 1.55) and obese (OR 1.44, 95% CI 1.21 to 1.72) women were more likely to report SUI (Zhu et al, 2008).

In a randomized clinical trial of women with type 2 DM—the Action for Health in Diabetes (Look AHEAD) study—obese (BMI

>35 kg/m²) women were more likely to experience both SUI and overall incontinence (Phelan et al, 2009). In a randomized clinical trial of hormone replacement in postmenopausal women—the Heart and Estrogen/progestin Replacement Study (HERS)—BMI and waist-to-hip ratio were each directly associated with SUI risk; BMI was also associated with mixed incontinence (Brown et al, 1999).

In a survey of 6000 women living in the Pacific Northwest region of the United States, BMI greater than or equal to 30 kg/m² was associated with an increased risk of self-reported urinary incontinence (OR 2.39, 95% CI 1.99 to 2.87) (Melville et al, 2005). Finally, in a cross-sectional analysis of nearly 4000 women in southern California, obesity was associated with SUI in both nondiabetic (OR 2.62, 95% CI 2.09 to 3.30) and diabetic (OR 3.67, 95% CI 2.48 to 5.43) participants (Lawrence et al, 2007).

Obesity: Weight Loss and Urinary Incontinence

SUI in women is one of the few urologic conditions for which level I evidence exists favoring an intervention that, by targeting a feature of MetS, improves the urologic condition. The Program to Reduce Incontinence by Diet and Exercise (PRIDE) trial randomized overweight or obese women who experienced 10 or more incontinence episodes per week to either an intensive 6-month behavioral weight loss intervention or a structured educational program. Women in the behavioral intervention group lost more weight and showed significant improvements in SUI (but not urge incontinence) compared to those in the education group (Subak et al, 2009). Two systematic reviews also concluded that weight loss improves SUI in women (Hunskaar, 2008; Imamura et al, 2010).

Based on these data, the 2012 European Association of Urology Guidelines on Urinary Incontinence concluded that evidence in support of weight loss as an effective lifestyle intervention for incontinence was Grade A, and the recommendations also encouraged “obese women suffering from any urinary incontinence to lose weight (>5%)” (http://www.uroweb.org/gls/pdf/18_Urinary_Incontinence_LR.pdf). The extent to which urologists and other health care providers have adopted this recommendation, and routinely use weight loss as a first-line intervention for incontinence in obese women, is unknown. The American Urological Association guidelines have not as yet addressed the topic of lifestyle interventions and urinary incontinence (www.auanet.org).

Diabetes and Disruptions in Glucose Homeostasis

In the southern California study, nonobese women with type 2 DM were 80% more likely to report SUI (OR 1.81, 95% CI 1.09 to 3.00) (Lawrence et al, 2007). In HERS, DM was associated with a 49% increased risk of urge incontinence (OR 1.49, 95% CI 1.11 to 2.00) and a 32% increased risk of mixed incontinence (OR 1.04, 95% CI 1.11 to 2.00) (Brown et al, 1999).

Metabolic Syndrome and Urinary Stones

MetS has been associated with an increased risk of urinary lithiasis. Putative causal factors include decreased urine pH, hypercalciuria, hyperuricosuria, and hyperoxaluria (Gorbachinsky et al, 2010).

Metabolic Syndrome

Studies have shown robust associations of MetS with an increased prevalence of urinary stones in U.S., European, and Southeast Asian populations. In the U.S. NHANES, the prevalence of self-reported history of kidney stones in an analytic cohort of 14,870 men and women increased substantially with the presence of increased MetS components, with a prevalence of 3%, 7.5%, and 9.8% in participants with 0, 3, and 5 components, respectively. Multivariable adjustment showed further that the presence of greater than or equal to 2 components significantly increased the odds of kidney stones, and that the presence of greater than or equal to 4 components increased the odds approximately twofold (West et al, 2008).

In a study of a screened Korean population (n = 34,895), those with MetS showed a 25% increase in the multivariable adjusted odds (OR 1.25, 95% CI 1.03 to 1.50) in kidney-stone prevalence as detected with computed tomography or ultrasound.

Finally, in an Italian study (n = 2132) of hospitalized patients, MetS was associated with a twofold adjusted risk in the prevalence of ultrasound-detected kidney stones (OR 2.62, 95% CI 1.50 to 4.64) (Rendina et al, 2009).

Obesity

Increased waist circumference and BMI have been independently associated with an increased risk of urinary stones. In an analysis that combined the U.S. Health Professionals Follow-up Study (n = 45,988 men), the Nurses' Health Study I (n = 93,758), and the Nurses' Health Study II (n = 101,877), male participants with a BMI greater than or equal to 30 kg/m² showed a 33% increased risk of incident stone disease compared to those with a BMI of 21 kg/m² to 22.9 kg/m² (relative risk [RR] 1.33, 95% CI 1.08 to 1.63; *P* < .001 for trend). For the same categories of BMI in older and younger women, the increased risks were 90% (RR 1.90, 95% CI 1.61 to 2.25; *P* < .001 for trend) and more than twofold (RR 2.09, 95% CI 1.77 to 2.48; *P* < .001 for trend), respectively. Waist circumference was also positively associated with an increased risk of stones in both men (*P* = .002 for trend) and women (*P* < .001) (Taylor et al, 2005b).

In a study of 95,598 patients in a U.S. health administrative database, obesity was associated with a significantly increased risk of kidney-stone diagnosis at all stratifications comparing obese to nonobese patients. The odds generally increased with increasing BMI. Compared to men with BMI less than 20, those with a BMI of 45.0 to 49.9 had more than a threefold risk of stone diagnosis (OR 3.18, 95% CI 1.61 to 6.29; *P* < .0009) (Semins et al, 2010).

In the aforementioned Korean study, the adjusted odds for kidney stones increased with an increasing quintile of waist circumference (*P* < .001).

Diabetes and Disruptions in Glucose Homeostasis

In another analysis combining more than 200,000 participants in the Health Professionals Follow-up Study and Nurses' Health Studies I and II, DM was associated with an increased adjusted prevalence of stone disease in all groups, with increased risks of 38% (RR 1.38, 95% CI 1.06 to 1.79) in older women, 67% (RR 1.67, 95% CI 1.28 to 2.20) in younger women, and 31% (RR 1.31, 95% CI 1.11 to 1.54) in men.

Similarly, in a prospective analysis of the same cohorts, the adjusted stone incidence was greater in female participants with DM compared to those without: a 29% (1.29, 95% CI 1.05 to 1.58) and a 60% (1.60, 95% CI 1.16 to 2.21) increased risk in older and younger women, respectively. Although there was no association of DM with incident kidney-stone risk in men (RR 0.81, 95% CI 0.59 to 1.09), men with kidney stones at baseline were 49% more likely to develop incident DM (RR 1.49, 95% CI 1.29 to 1.72) than those without kidney stones, as were both older (1.33, 95% CI 1.18 to 1.50) and younger (1.48, 95% CI 1.14 to 1.91) women, respectively.

These investigators speculated that the association of stone disease with incident DM was potentially linked to subclinical insulin resistance (Taylor et al, 2005a).

Elevated Blood Pressure

In the Korean study, participants with HTN showed a 47% increased adjusted risk of kidney stones (1.47, 95% CI 1.25 to 1.71) compared to participants without HTN, and the multivariable-adjusted odds for kidney stones increased with increasing quintile of blood pressure (*P* < .001).

In a study of Italian male factory workers, those with HTN showed an unadjusted increased risk of a history of kidney stones compared to those without HTN (OR 2.11, 95% CI 1.17 to 3.81), which was even higher in men with treated HTN (OR 3.16, 95% CI

1.75 to 5.71). Men with treated HTN also had an increased, if slightly attenuated, age-adjusted kidney-stone risk (OR 2.63, 95% CI 2.23 to 3.10) (Cappuccio et al, 1990).

In a prospective study of the same population followed for 8 years, those with HTN at baseline were approximately twice as likely to develop kidney stones (Cappuccio et al, 1999).

Other studies have shown that nephrolithiasis is a risk factor for the development of HTN, suggesting that these associations are bidirectional (Madore et al, 1998a, 1998b).

Metabolic Syndrome and Erectile Dysfunction

The presence of MetS, each of the five individual components of MetS, and CVD all substantially increase the risk of ED. Several different etiologies are likely involved, including but not necessarily limited to the following: inhibition of nitric oxide synthase pathways; MetS-associated hypogonadism; atherosclerosis-mediated vasculopathy; disruption of autonomic signaling pathways; and promotion of corporal cavernosal fibrosis (Gorbachinsky et al, 2010).

Metabolic Syndrome and Cardiovascular Disease

Multiple studies worldwide have included observations showing a significantly increased prevalence of ED among men with a diagnosis of MetS, including a German health screening project of 2371 men ($P = .01$), a case control analysis of Italian men ($P = .03$), a cohort of 393 Turkish men ($P < .001$), a separate cohort of 268 Turkish men ($P < .001$), and a primary case-based population of 3921 Canadian men (Esposito et al, 2005; Grover et al, 2006; Bal et al, 2007; Heidler et al, 2007).

Moreover, ED appears to be an independent risk factor for incident CVD. In a study of more than 8063 men greater than or equal to age 55 years who were randomized to the placebo arm of the PCPT, those with incident ED experienced a 25% increased adjusted risk of incident CVD (defined as myocardial infarction or surgical treatment of coronary artery disease, angina, cerebrovascular accident, transient ischemic attack, congestive heart failure, or nonfatal cardiac arrhythmia requiring treatment) compared to those without ED (hazard ratio [HR] 1.25, 95% CI 1.02 to 1.53). Men with either incident or prevalent ED experienced a 45% increased adjusted risk (HR 1.45, 95% CI 1.25 to 1.69). The magnitudes of these risks were similar to those observed for current smoking or a family history of myocardial infarction (Thompson et al, 2005).

Similar conclusions were reported in other studies (Montorsi et al, 2006; Inman et al, 2009). ED has also been associated with subclinical atherosclerosis (Chiurlia et al, 2005), endothelial dysfunction (Yavuzgil et al, 2005), and reduced brachial artery vasodilation (Kaiser et al, 2004).

Nevertheless, although these data thus implicate ED as an independent risk factor for clinically significant CVD, the validity of routinely using ED for CVD screening has not been defined (Alhathal and Carrier, 2011; Ewane et al, 2012), and formal guidelines as yet do not exist.

Obesity

Obesity—including central obesity as measured by waist circumference—was one of the first modifiable risk factors linked to ED (Derby et al, 2000; Feldman et al, 2000; Bacon et al, 2003; Fung et al, 2004; Carvalho et al, 2013).

Obesity: Weight Loss, Exercise, and Erectile Dysfunction

Similar to SUI in obese women, level I evidence indicates that a lifestyle intervention aimed at weight loss improves erectile function in obese men. In an Italian randomized clinical trial, 110 obese men (BMI ≥ 30 kg/m²) aged 35 to 55 years with ED as determined by IIEF score and without DM, HTN, or hyperlipidemia were randomized to either an intensive weight loss intervention of caloric reduction and exercise or a control state that provided general

information about healthy food choices and exercise. After 2 years, men in the intervention group had lost more weight, were more physically active, and reported significantly larger increases in IIEF score than those in the control group. Moreover, in multivariate analyses, changes in BMI ($P = .02$) and physical activity ($P = .02$) were independently associated with changes in IIEF score (Esposito et al, 2004).

It is not clear to what extent these data are applied in the clinical management of ED. The American Urological Association Guidelines for the Management of Erectile Dysfunction did not formally address the use of weight loss or other lifestyle interventions in the management of ED (www.auanet.org).

Diabetes and Disruptions in Glucose Homeostasis

Although diabetes is a well-established risk factor for ED (Feldman et al, 1994, 2000; Maiorino et al, 2014), data have also shown links between ED and prediabetic states characteristic of MetS. In a cohort of Argentinian men, ED was associated with an increased risk of insulin resistance, defined as homeostasis model assessment greater than or equal to 3 ($P = .04$) (Knoblovits et al, 2010). Similarly, in a cohort of Chinese patients, ED was also associated with insulin resistance, defined as quantitative insulin sensitivity check index less than or equal to 0.357 (Chen et al, 2013).

Elevated Blood Pressure

Men with HTN are more likely to experience ED than those without HTN (Feldman et al, 1994; Saigal et al, 2006).

Metabolic Syndrome and Male Infertility

MetS and its components are associated with an increased risk of infertility. Several factors may potentially contribute to male infertility in the setting of MetS and its components, including associations of obesity with spermatic DNA damage, low ejaculate volume, and diminished sperm motility, volume, and count; associations of type 2 DM with lower sperm motility, semen volume, and ejaculatory dysfunction; and associations of MetS with hypogonadism (Fig. 23-3) (Gorbachinsky et al, 2010).

Obesity

A systematic review and meta-analysis of BMI and sperm count, which included 21 studies and 13,077 men, reported the conclusion that compared to men of normal weight, overweight (OR 1.28, 95% CI 1.06 to 1.55) and obese (OR 2.04, 95% CI 1.59 to 2.62) men were more likely to have oligozoospermia or azoospermia (Sermondade et al, 2013).

In a Norwegian study of 26,303 planned pregnancies, overweight (BMI 25 to 29.9 kg/m²) and obese (BMI 30 to 34.9 kg/m²) men were 20% (OR 1.20, 95% CI 1.04 to 1.38) and 36% (OR 1.36, 95% CI 1.13 to 1.63) more likely, respectively, to report infertility, defined as a need for up to 12 months to achieve pregnancy or a need for infertility treatment (Nguyen et al, 2007).

Similarly, in a prospective Japanese study of 74 healthy men, those with higher BMI were 20% less likely (HR 0.80, 95% CI 0.67 to 0.95) to father a child during a median follow-up period of 20 months (Ohwaki et al, 2009).

Finally, among an analytic sample of 1329 men enrolled in the U.S. Agricultural Health Study, a 3-unit increase in BMI was associated with a 12% increased adjusted risk (OR 1.12, 95% CI 1.01 to 1.25) of infertility, defined as not conceiving after 12 or more months of unprotected intercourse, regardless of whether or not a pregnancy subsequently occurred (Sallmén et al, 2006).

Diabetes and Disruptions in Glucose Homeostasis

In a cross-sectional study of 857 men in Qatar, those with type 2 DM were more likely to be diagnosed with infertility ($P = .003$).

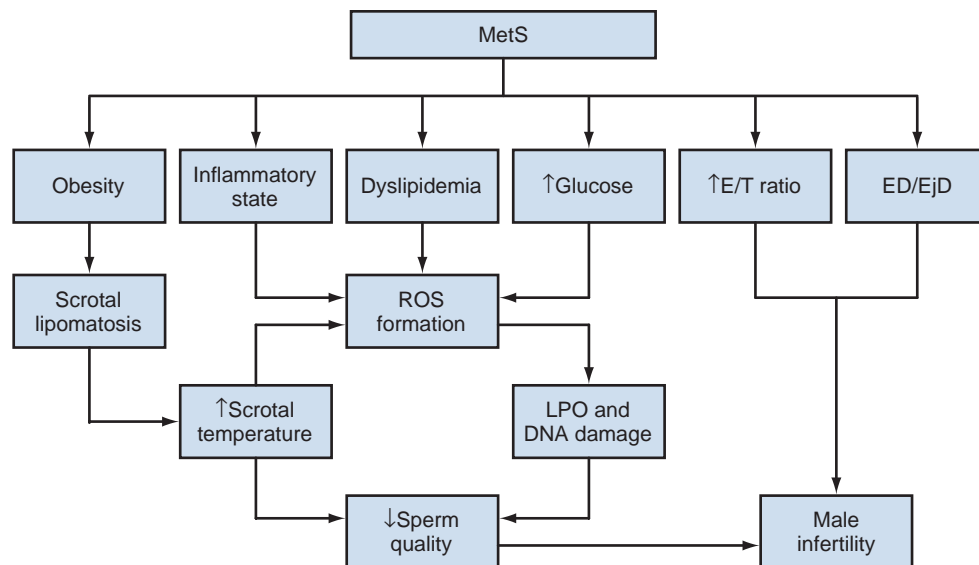

Figure 23-3. Possible mechanisms of male infertility in metabolic syndrome (MetS). DNA, deoxyribonucleic acid; ED/EjD, erectile dysfunction/ejaculatory dysfunction; E/T, estrogen/testosterone; LPO, lipid peroxidation; ROS, reactive oxygen species. (Modified from Gorbachinsky I, Akpinar H, Assimos G. Metabolic syndrome and urologic diseases. *Rev Urol* 2010;12:e157–e180.)

However, in reaching this conclusion, these investigators did not provide specific definitions for infertility nor did they control for potential confounders such as obesity. Indeed, the men with type 2 DM were more likely to be obese ($P = .073$), and in a multivariable-adjusted subgroup analysis of men with type 2 DM, obesity was strongly associated with infertility (OR 3.36, 95% CI 1.81 to 6.23), suggesting that obesity may have confounded the association of DM with infertility in these men (Bener et al, 2009).

Metabolic Syndrome and Urologic Cancers

Associations of MetS with urologic cancers are beginning to emerge, with epidemiologic studies indicating that some aspects of MetS may influence the natural histories of prostate, kidney, and bladder cancer. However, some of these data are conflicting, and not all risk patterns are entirely clear.

Prostate Cancer

The findings for prostate cancer are perhaps the most puzzling, with studies showing MetS associated with both increased and decreased risks of incident prostate cancer. In addition, obesity increases the risk of incident high-grade disease and biochemical recurrence after primary therapy, but decreases the risk of incident low-grade disease. DM decreases the risk of incident disease. Some investigators have speculated that these contradictory observations result from differential effects of different MetS components on the pathogenesis of prostate cancer (Buschemeyer and Freedland, 2007; De Nunzio et al, 2012).

Kidney Cancer

The most extensively studied MetS factor for kidney cancer is obesity, which has been associated with increased risks of disease prevalence and incidence (Chow et al, 2010; Ljungberg et al, 2011; Hakimi et al, 2013). In addition to obesity, at least one study—a cohort analysis of 560,388 men and women from Norway, Austria, and Sweden—indicated an increased risk of incident renal cell carcinoma with increased systolic or diastolic blood pressure, blood glucose, triglycerides, and a composite metabolic score that assessed the combined effects of adiposity, blood pressure, glucose, and triglycerides (Hägström et al, 2013).

Bladder Cancer

Several studies have focused on obesity, DM, and bladder cancer. A meta-analysis of 11 cohort studies noted a modest, but significant, increased risk of bladder cancer incidence and prevalence for obesity (Qin et al, 2013). A meta-analysis combining 36 studies observed an increased risk of bladder cancer among diabetics, with an overall increased risk of 35% compared with nondiabetics (RR 1.35, 95% CI 1.17 to 1.56), although men predominantly drove the risk (Zhu et al, 2013).

KEY POINTS: METABOLIC SYNDROME AND UROLOGIC DISEASES

- MetS is a constellation of clinical factors associated with an increased risk of incident CVD and diabetes.
- At least three of the following factors must be present to render a diagnosis of MetS:
 - Abdominal obesity
 - Elevated blood glucose
 - Elevated blood pressure
 - Elevated serum triglycerides
 - Decreased HDL cholesterol
- Men's health integrates male urologic care with the prevention and treatment of systemic CVD. It is an evolving paradigm with no clearly defined clinical parameters.
- There are no formal guidelines for the evaluation or treatment of MetS in the practical management of urologic conditions.
- MetS and its components are associated with increased risks of the following urologic conditions:
 - BPE and male LUTS
 - Female urinary incontinence
 - Urinary stones
 - ED
 - Male factor infertility
 - High-grade prostate cancer
 - Kidney cancer
 - Bladder cancer
- Weight loss improves continence in obese women with SUI.
- Weight loss improves erectile function in obese men with ED.

Diagnoses and Therapies

EPIDEMIOLOGY

The disease of infertility affects approximately 15% of couples, rendering nearly one of six childless ([World Health Organization \[WHO\], 1991](#)). Multiple sources of bias historically have served to distort assessment of the contribution of each gender to infertility, but we can reasonably expect men to contribute equally to women when it comes to whose gametes are faulty ([Tielemans et al, 2002](#)). Hence, accurate evaluation and treatment of the man becomes of great importance in addressing a significant health care issue.

Unfortunately, much of infertility care for men is delivered outside of well-established reimbursement systems, frustrating accurate calculation of epidemiologic metrics ([Meacham et al, 2007](#)). Fortunately, the American Society for Reproductive Medicine's professional group, the Society for Assisted Reproductive Technologies (SART), compels in vitro fertilization (IVF), clinics to report outcomes in a systematic fashion, allowing limited evaluation of the impact of male infertility. However, this assessment is through the lens of women seeking the most evolved technology for female reproductive care and necessarily skews the appraisal of the incidence and prevalence of the male contribution to the disease.

The Urologic Diseases in America (UDA) Project included collection of male reproductive epidemiologic data from a variety of sources, which, albeit sparse, allowed for some limited analysis of the parameters of the disease of male infertility ([Meacham et al, 2007](#)). Considering ambulatory surgery for conditions associated with male infertility, it is unsurprising that men aged 25 to 34 years had higher usage with an average rate of 126 per 100,000 compared with men aged 35 to 44 with 83 per 100,000 and those aged 45 and older at 20 per 100,000 ([Meacham et al, 2007](#)). Thus, younger men represent over half of male infertility cases, and nearly one in 11 cases occurs in men in the fifth decade and older ([Meacham et al, 2007](#)). Considering geographic distribution in the United States, men living in the West had lower use of ambulatory surgery compared with those in the Northeast and Midwest (29 per 100,000, 104 per 100,000 and 72 per 100,000, respectively) ([Meacham et al, 2007](#)).

From an economic perspective, the UDA Project estimated total expenditures for treating primary male infertility at 17 million U.S. dollars (USD) in the year 2000, clearly an underestimate because of the delivered care absent from traditional databases ([Meacham et al, 2007](#)). Because a significant amount of male reproductive medical care delivery involves assisted technologies for the female partner, accounting for this care the assessed total cost is a sizable 18 billion USD ([Meacham et al, 2007](#)).

Complicating epidemiologic assessment is the fact that the primary assay for male infertility, the semen analysis, is a poor predictor with a low receiver operating characteristic (ROC) curve area for all available parameters ([Guzick et al, 2001](#)). Consequently, men with some presence of sperm on semen analysis may be inaccurately judged to be fertile and omitted from accurate accrual in a tabulation of insufficient reproductive potential.

HISTORY

The production and delivery of the male gamete requires high orchestration among endocrine, immune, and neural systems, passage through intricately constructed anatomy, complex orchestrated sequences of gene expression and chromosomal structural events, and the proper embryologic and postnatal development of all systems. It is consequently unsurprising that myriad disparate conditions contribute to male reproductive dysfunction. [Table 24-1](#) enumerates percentages of final diagnoses made in one infertility clinic ([Sigman et al, 2009](#)). As will become clear in this chapter, the percentages in [Table 24-1](#) for each condition are highly variable depending on how the individual conditions are assessed in published studies, and the data contained within the table are an indictment of how poorly male reproductive information is systematically collected. However, the table does demonstrate the wide variety of diagnoses associated with male infertility. To address all potential possibilities, the practitioner must approach inquiring about past history in a methodical fashion. For the sake of efficiency, the patient may complete a form at home or in the waiting area before the physician encounter.

Reproductive health is an unusual aspect of medicine in that two patients are required for a positive outcome. Several consequences arise from this unique circumstance, the first being that a probabilistic approach to diagnosing infertility is necessary. In the best circumstances, with intercourse timed to menstruation and a rigorous calculation of optimal timing including assessment of quality of cervical mucus and measurement of basal body temperature, cumulative pregnancy rates for all tracked subjects in one well-conducted study were 38% at one cycle, 68% at three cycles, 81% at six cycles, and 92% at 12 cycles ([Gnoth et al, 2003](#)). For those who ultimately became pregnant, the cumulative pregnancy rates were 42% at one cycle, 75% at three cycles, 88% at six cycles, and 98% at 12 cycles ([Gnoth et al, 2003](#)). Hence, a couple seeking treatment for infertility a month or two after discontinuing contraceptive measures should be counseled to continue to try for a few more months unless other significant conditions exist. A **minority of**

TABLE 24-1 Distribution of Final Diagnoses from a Male Infertility Clinic

CATEGORY	NUMBER	%
Immunologic	121	2.6%
Idiopathic	1535	32.6%
Varicocele	1253	26.6%
Obstruction	720	15.3%
Normal female factor	503	10.7%
Cryptorchidism	129	2.7%
Ejaculatory failure	95	2.0%
Endocrinologic	70	1.5%
Drug or radiation	64	1.4%
Genetic	56	1.2%
Testicular failure	52	1.1%
Sexual dysfunction	32	0.7%
Pyospermia	25	0.5%
Cancer	20	0.4%
Systemic disease	15	0.3%
Infection	10	0.2%
Torsion	5	0.1%
Ultrastructural	5	0.1%
TOTAL	4710	100.0%

From Sigman M, Lipshultz LI, Howards SS. Office evaluation of the subfertile male. In: Lipshultz LI, Howards SS, Niederberger CS, editors. Infertility in the male. 4th edition. New York: Cambridge University Press; 2009. p. 153–76.

couples who have not conceived after six cycles may still do so, and it is reasonable to initiate an evaluation after 6 months with the understanding that some couples will still conceive shortly afterward. It is useful to communicate to patients the probabilistic nature of reproduction by describing each month of trying as rolling a die or flipping a coin.

An important question to ask is how often the couple is having intercourse. In general, semen parameters peak after 1 or 2 days of abstinence and then decline (Levitas et al, 2005). Often in an attempt to accumulate sperm, men wait long periods before attempting to impregnate their partners. Data suggest that not only is this practice unhelpful, it actually results in poorer sperm quality (Levitas et al, 2005). For an optimal characterization of semen, a man should be instructed to wait 1 or 2 days after an ejaculation to submit a specimen for semen analysis (Levitas et al, 2005). However, for increasing the probability of conception and pregnancy, intercourse every day around the time of ovulation is likely the best strategy (Scarpa et al, 2007).

Another consequence of the fact that two patients are required for a positive outcome in this unique area of medicine is that consideration of the female partner's age is a critical component in judging reproductive potential and planning therapeutic strategies. Whereas the effects of male age on reproductive potential remain to be fully elucidated, advancing male age appears to affect bulk seminal parameters and sperm DNA packaging to only a limited degree, allowing a male to father children well into his later years (Henkel et al, 2005; Hellstrom et al, 2006; Moskovtsev et al, 2006; Schmid et al, 2007; Slotter et al, 2007; Yang et al, 2007; Cocuzza et al, 2008a; Colin et al, 2010; Silva et al, 2012). For the woman, age is a critical predictor of reproductive potential, especially when artificial reproductive technologies are used (te Velde and Pearson, 2002; Balasch and Gratacós, 2012). On average, female fecundity declines precipitously after age 35 (Balasch and Gratacós, 2012). In some geographic regions, female fertility appears to decline more rapidly than others (Zargar et al, 1997). Hence, determining the female partner's age and assessing it in the context of her locale are essential aspects of the reproductive history.

An important general question to ask is whether the man and his partner have previously conceived children, or if each has with other partners, and the age or ages of the offspring. Proven fertility at some point in time demonstrates a functioning reproductive system after puberty, which eliminates a number of concerns regarding congenital issues.

The typical enumeration of systemic diseases and past surgeries in taking the reproductive history reveals a number of conditions associated with reproductive dysfunction. Diabetes mellitus and multiple sclerosis interfere with normal coordinated ejaculatory function, as does spinal cord injury (Vinik et al, 2003; Kafetsoulis et al, 2006; Tepavcevic et al, 2008). Even before spermatotoxic chemotherapy, cancer itself appears to negatively affect spermatogenesis, especially if the cancer is of testicular origin (de Bruin et al, 2009). It is interesting to note that azoospermia may reveal cancer, and the physician considering a man with no sperm on semen analysis should regard testis cancer as a possible cause (Mancini et al, 2007). Surgeries such as transurethral resection of the prostate and minimally invasive therapies for prostatic enlargement are associated with ejaculatory dysfunction (Jaidane et al, 2010; Elshal et al, 2012). As discussed elsewhere in this text, retrograde ejaculation of varying degrees may occur after retroperitoneal lymph node dissection for testis cancer, depending on the type of dissection and the clinical context within which the dissection occurs.

Herniorrhaphy may result in obstruction of the vas deferens (Shin et al, 2005; Hallén et al, 2011, 2012; Tekatli et al, 2012). Mesh in particular appears to incite a dense foreign body inflammatory response that may entrap the vas deferens even if the placement of mesh is not be immediately adjacent to the vas (Maciel et al, 2007; Hallén et al, 2011, 2012; Tekatli et al, 2012). If vasal occlusion is the sole cause of infertility, then both vasa must be occluded, an expectedly infrequent event. However, occlusion of one vasa from herniorrhaphy with contralateral spermatogenic dysfunction of another source may serve as a cause of infertility in the male.

Aside from the typical questions regarding medical and surgical history, answers to a number of questions specifically related to male reproduction may elucidate causes of infertility. If the practitioner is not using a history form, a helpful mnemonic is *TICS*, as if one is ticking off items on a list. *T* stands for toxins, *I* for infectious disease, *C* for childhood history, and *S* for sexual history.

Spermatotoxicity

In the *TICS* mnemonic, *T* is for toxins. A variety of substances interfere with spermatogenesis, mature sperm function, and sperm delivery. Many common medications, prescribed and over the counter, can be associated with male reproductive dysfunction.

Endocrine Modulators

Medications may affect the ratio of estrogen to androgen through a variety of mechanisms, including a molecular similarity to estrogen, increased estrogen synthesis, increased aromatase activity, dissociation of steroids from sex hormone-binding globulin (SHBG), decreased testosterone synthesis, competitive and noncompetitive binding to steroid receptors, decreased synthesis of adrenal steroids, and induction of hyperprolactinemia (Bowman et al, 2012). Some of the more commonly encountered agents warranting inquiry include the antiandrogens bicalutamide, flutamide, and nilutamide; the antihypertensive spironolactone; the antiretroviral protease inhibitors such as indinavir; the nucleoside reverse transcriptase inhibitors such as stavudine; corticosteroids, especially in adolescence; and exogenous estrogen (Bowman et al, 2012).

Although a source of debate, the 5 α -reductase inhibitors finasteride and dutasteride appear to have only limited spermatogenic suppressive effects if at all (Overstreet et al, 1999; Amory et al, 2007). Occasional anecdotal case reports suggest that sperm parameters dramatically improve in an individual man after discontinuation of a 5 α -reductase inhibitor, but the substantial interassay

variability of semen parameters calls into question whether these effects could simply be the result of chance (Chiba et al, 2011).

Primarily through conversion to estradiol by aromatase and consequent inhibition of luteinizing hormone (LH) secretion by the pituitary, exogenous testosterone acts to decrease intratesticular testosterone synthesis and reduce spermatogenesis (Grimes et al, 2012). Agents with androgenic properties similarly diminish sperm production (de Souza and Hallak, 2011). In fact, investigators have studied testosterone and androgenic steroids as potential targets for male contraception since the 1970s (WHO Task Force, 1990; Gu et al, 2009; Grimes et al, 2012; Ilani et al, 2012). In general, these studies have a duration of 2 years or less of application of testosterone or androgenic steroid and demonstrate reversibility with return to sperm in the ejaculate after approximately 4 months or more of discontinuation of the contraceptive agent (WHO Task Force, 1990; Gu et al, 2009; Grimes et al, 2012; Ilani et al, 2012). However, whether and when spermatogenesis returns after longer periods of use is unknown.

Recreational Drugs

Although data are conflicting, most studies suggest that cannabis decreases plasma testosterone in a dose-dependent and duration-dependent manner (Gorzalka et al, 2010). More robust data associate chronic alcohol intake with decreases in androgens and sperm parameters (Villalta et al, 1997; Pasqualotto et al, 2004). Heavy chronic alcohol intake also appears to increase aromatization of testosterone to estradiol (Purohit, 2000). Investigators have observed that more moderate use of alcohol may decrease intracytoplasmic sperm injection (ICSI) outcomes (Braga et al, 2012).

Early studies suggested worsening of bulk seminal parameters with cigarette smoking (Stillman et al, 1986). Although the results of subsequent studies associating smoking and bulk parameters were conflicting, more recent cross-sectional analysis has supported deterioration of seminal parameters in a dose-dependent manner, arguing more strongly that cigarette smoking impairs male reproductive potential (Ramlau-Hansen et al, 2007). Investigators observed that cigarette smoking increased seminal oxidative stress parameters and decreased metrics of sperm DNA quality (Pasqualotto et al, 2008b; Taha et al, 2012). An abnormal ratio of protamines 1 and 2 was observed in smokers with evidence of atypical protamine 2 expression, pointing to DNA packaging as directly compromised by tobacco use (Hammadeh et al, 2010). The negative effects of cigarette smoking on sperm bulk parameters and DNA quality appear to be especially acute in the presence of a clinical varicocele, suggesting the possibility of additive toxicity (Fariello et al, 2012b). Researchers studied effects of an aryl hydrocarbon receptor ligand present in cigarette smoke and found that it induced apoptosis in fetal testis in a manner that was preventable with an aryl hydrocarbon receptor antagonist, providing evidence that maternal smoking may affect the reproductive potential of male offspring (Coutts et al, 2007). Consistent with these laboratory findings, epidemiologic data associated maternal cigarette smoking to smaller testes, lower sperm counts, and alterations in sex hormones in the adult male offspring (Jensen et al, 2005; Ravnborg et al, 2011). It is interesting to note that epidemiologic evidence supports that the secondary sex ratio, the ratio of boys to girls born, is altered in mothers who smoke (Beratis et al, 2008). One explanation is that cigarette smoking alters circulating testosterone concentrations in pregnant women (James, 2002).

Antihypertensives

Please see the Expert Consult website for details.

Antipsychotics

The most common mechanism of action for antipsychotic drugs is antagonism of dopamine, which causes loss of libido as a side effect in the majority of patients (Stimmel and Gutierrez, 2006). Another proposed reason for diminished libido with use of antipsychotics

is elevation of prolactin levels, which appears to be most acute for risperidone and to a lesser extent olanzapine (Melkersson, 2005). As discussed elsewhere in this text, selective serotonin reuptake inhibitors (SSRIs) are commonly associated with anorgasmia and delayed or absent ejaculation (Clayton and Montejo, 2006; Stimmel and Gutierrez, 2006).

Opioids

Opioid analgesics suppress LH release primarily through hypothalamic-mediated mechanisms and consequently reduce testosterone synthesis (Subirán et al, 2011). Experimental evidence in animals demonstrates endogenous opioid peptides, their precursors, and their receptors in various testis cell types (Subirán et al, 2011). Endogenous opioid peptides are primarily synthesized by Leydig and Sertoli cells and inhibit Sertoli cell function, via autocrine and paracrine mechanisms (Subirán et al, 2011). Hence, not only can opioids induce the hypogonadotropic hypogonadism commonly observed in chronic use, they may also diminish spermatogenesis directly in the testis (Brennan, 2013; Subirán et al, 2011). Evidence suggests that discontinuation of opioid analgesics may be associated with rapid return of androgen, perhaps as early as within 1 month (Brennan, 2013). With the widespread prescribing of opioid analgesics, their use as a cause of hypogonadotropic hypogonadism should be suspected in all such hypoandrogenic men.

Antibiotics

Please see the Expert Consult website for details.

Cytotoxic Chemotherapeutics

Because chemotherapeutic agents are most effectively applied to suppress a briskly proliferating population of cells, and the pathway of male gamete development primarily involves a rapidly dividing stem cell cohort, it is unsurprising that medical therapies directed toward cancers impair spermatogenesis. Alkylating agents such as the nitrogen mustard cyclophosphamide have been long identified to impair sperm production (Vaisheva et al, 2007). These spermatogenic suppressive effects were noted to be dose and time dependent, with lower doses and shorter durations of therapy leading to reversible dysfunction but ultimate return to male fertility potential, and higher doses and longer durations of therapies resulting in permanently impaired fertility (Vaisheva et al, 2007). Other chemotherapeutic agents commonly used in conjunction with cyclophosphamide to treat non-Hodgkin lymphoma, including doxorubicin, vincristine, and prednisone, have all been reported to impair spermatogenesis as individual agents (Vaisheva et al, 2007). Likewise, investigators reported that cisplatin, etoposide, and bleomycin were associated with diminished sperm parameters in a dose- and time-dependent manner (Gandini et al, 2006).

One concern of both patients and physicians is how much chemotherapy damages the DNA of sperm (Robbins, 1996; Spermon et al, 2006; Stahl et al, 2006; Delbes et al, 2007; O'Flaherty et al, 2008; Tempest et al, 2008; O'Flaherty et al, 2010; Smit et al, 2010). Evidence suggests that sperm DNA damage can be detected at least up to 2 years after chemotherapy, arguing that cryopreservation of sperm before treatment with cytotoxic chemotherapeutic agents is preferable to awaiting the return of sperm after chemotherapy (Tempest et al, 2008). The question is whether sperm is "safe" to use after a discrete amount of time after the induction of chemotherapeutic agents that might mutate cellular DNA in a way that may be translated through the germ line into offspring. An informed answer to that question based on well-conducted clinical trials is not yet available. This lack of knowledge frustrates male reproductive specialists who counsel patients on whether their own biologic material or donor sperm would be the best choice after cytotoxic chemotherapy. Questions about sperm DNA integrity and mutagenicity after chemotherapy serve as a second reason to encourage men undergoing such oncologic therapy to cryopreserve

The relationship between antihypertensive medication and erectile dysfunction is well known and discussed elsewhere in this text. The direct effects of antihypertensives on male reproductive function is less clear. Investigators have proposed that calcium channel blockers impair fertilization by inhibiting expression of mannose-ligand binding receptors and preventing sperm from attaching to the zona pellucida ([Benoff et al, 1994](#)). Although laboratory evidence supports this hypothesis, limited clinical data from IVF cycles question whether calcium channel blockers affect fertilization at all ([Katsoff](#)

[and Check, 1997](#)). It is interesting to note that angiotensin-converting enzyme inhibitors appear to improve sperm motility through a presumptive effect on seminal plasma kinins ([Somlev and Subev, 1998](#)). In a limited controlled clinical trial with cross-over design, 2.5 mg of lisinopril daily increased sperm count, motility, and morphology ([Mbah et al, 2012](#)). If these results are replicated in larger future studies, they suggest an effect beyond that of altering seminal plasma characteristics alone.

Data derived from animal studies indict drugs in each of the major classes of antibiotics as toxic to spermatogenesis or sperm function (Schlegel et al, 1991). However, evidence broadly suggesting male reproductive toxicity for antibiotics in humans is, in general, lacking. Animal studies and limited human data demonstrate testis dysfunction and reduced spermatogenesis with tetracycline, potentially through an oxidative stress mechanism (Kushniruk, 1973; Schlegel et al, 1991; Pasqualotto et al, 2004; Farombi et al, 2008). Because tetracycline binds mature sperm, direct toxicity on sperm function is also possible (Pasqualotto et al, 2004). It is

interesting to note that spermatotoxic effects of tetracycline may be paternally transmitted to male offspring (Zeh et al, 2012). Investigators observed in animals that high doses of nitrofurantoin reduced epididymal sperm density and sperm motility (Chapin et al, 1997). In humans, male reproductive toxicity of nitrofurantoin is unclear in the typical dose range for a discrete duration. Surgeons irrigating vasa with nitrofurantoin solution reported spermatotoxicity in the immediate postoperative period, but this experimental model does not accurately mimic the typical pharmacodynamic distribution of the drug (Albert et al, 1975).

sperm before induction, because cryopreservation presents a well-established means for fertility preservation in the setting of cancer (Anger et al, 2003; Meseguer et al, 2006; Crha et al, 2009). Proper cryopreservation of sperm results in long-term potential for reproductive success, and patients may be assured that should they store sperm in this way, it will be available when they need it (Rofeim and Gilbert, 2005). Although many patients may recover sperm in the ejaculate after cytotoxic chemotherapy, and it is very possible that, after a period as yet to be determined, ejaculated sperm after chemotherapy will be safe for conception, many men do not develop sufficient ejaculated sperm for fertility. These men do use cryopreserved sperm if available to successfully father offspring (Meseguer et al, 2006).

Systemic application of antitumor medication is not necessarily the only form of chemotherapy that may alter fertility potential. Investigators noted in a small series of young men that local instillation of bacille Calmette-Guérin into the bladder for superficial transitional cell carcinoma resulted in a significant decrease in sperm concentration and motility (Raviv et al, 2005).

A special case arises in peripubertal boys undergoing cytotoxic chemotherapy for cancer. Oncologists are often in a rush to apply lifesaving therapy, and parents may be uncomfortable discussing topics such as masturbation for semen collection with their children. However, if oncologic therapy is successful, it is precisely these patients with a potentially long life expectancy who would benefit from sperm cryopreservation as an option for future fertility. Peripubertal boys are capable of producing semen samples suitable for cryopreservation, and it is entirely feasible to obtain an ejaculate suitable for storage (van Casteren et al, 2008; Menon et al, 2009). The urologist need simply be comfortable enough to discuss the advantages of fertility preservation and the methods to achieve it.

Thermal Toxicity

For reasons not entirely clear but engendering much speculation, mammals evolved so that the scrotal container of the testis was housed outside the body cavity, keeping its contents at a temperature considerably cooler than that of the internal organs (Setchell, 1998; Thonneau et al, 1998). Scrotal temperature in humans is maintained to be 2° C to 4° C below core body temperature by mechanisms including a counter-current heat exchange between a central set of linear arteries directing blood toward the testis and a plexus of veins surrounding the arteries draining blood back toward the vena cava (Setchell, 1998; Thonneau et al, 1998). Many investigators have exhaustively studied the effects of heat on spermatogenesis in animals, observing depopulation of germ cells, perturbations in the various spermatogenic cell types, and apoptosis within specific cell types (Setchell, 1998; Absalan et al, 2010). Cryptorchidism provides a model by which the effects of heat can be studied on sperm production: increasing testis temperature to that of the abdominal cavity significantly impairs spermatogenesis (Setchell, 1998).

The degree to which scrotal temperature can be raised without affecting male fertility remains an open question. Clothing, physical activity, and body posture such as whether the legs are crossed or not in a sitting position all change scrotal temperature to an incremental degree, but whether that translates to alterations in spermatogenesis is purely speculative at this point (Jung et al, 2005; Miesusset et al, 2007). Researchers observed an increase in scrotal

temperature on the order of a half a degree Celsius with prolonged sitting on heated car seats, and speculated that such an effect may be additive to the intrascrotal temperature rise that occurs when sitting (Jung et al, 2008). One study observed that when a man was naked, mean scrotal temperature was significantly lower on the left than on the right, but when he was clothed, the temperature was significantly higher on the left than on the right (Bengoudifa and Miesusset, 2007). Clothing may thus confer a greater differential increase in left scrotal temperature than right scrotal temperature (Bengoudifa and Miesusset, 2007).

A number of studies associate occupational exposure resulting in a significant increase in intrascrotal temperature with detrimental effects on sperm (Thonneau et al, 1998; De Fleurian et al, 2009). However, other researchers have observed no significant negative effects on sperm in fertile men exposed to high heat at work, and postulated that in the normal state, compensatory mechanisms protect the testis when a prolonged rise in ambient temperature occurs (Momen et al, 2010).

Laptop computers radiate heat, and researchers have studied the effects of these devices on scrotal temperature. In one study, under controlled conditions, having a laptop computer resting on the lap for 1 hour raised the scrotal temperature an average 2.6° C on the left and 2.8° C on the right side (Sheynkin et al, 2005). However, simply sitting without a laptop raised the scrotal temperature an average of 2.1° C (Sheynkin et al, 2005). Whether the extra approximately half-degree Celsius imparts significant damage to spermatogenesis remains an open question. However, investigators have observed that a man sitting with his legs apart and for shorter periods of time experiences less of an increase in scrotal temperature (Sheynkin et al, 2011).

Radiation

Testes directly exposed to ionizing radiation suffer germ cell loss and Leydig cell dysfunction (Clermont, 1972; Castillo et al, 1990; Bahadur and Ralph, 1999; Gandini et al, 2006; Green et al, 2010). In one survey of boys with acute lymphoblastic leukemia who underwent testicular irradiation at 12, 15, and 24 Gray (Gy), all became azoospermic, but those receiving less than 24 Gy had normal testosterone production (Castillo et al, 1990). The investigators observed elevated gonadotropins and noted that this finding indicated the possibility of subclinical Leydig cell damage (Castillo et al, 1990). In a survey of childhood cancer survivors, chances of having future offspring were lessened by radiation doses to the testes of 7.5 Gy and above (Green et al, 2010). The testis need not be directly irradiated for spermatogenic impairment to occur; if the radiation field is proximal to the testis and the dose is sufficient, sperm production may be diminished even if the testis is shielded (Gandini et al, 2006).

With widespread use of radiofrequency devices for telecommunications and wireless networks, investigators have questioned the effects of this band of the electromagnetic spectrum on sperm (Erogul et al, 2006; Agarwal et al, 2008b; Baste et al, 2008; Falzone et al, 2008; Agarwal et al, 2009). Researchers observed negative effects on sperm motility parameters, viability, and reactive oxygen species (ROS) generation after electromagnetic radiation generated by 850- and 900- MHz cell phone transmission systems in vitro (Erogul et al, 2006; Falzone et al, 2008; Agarwal et al, 2009). However, in vitro exposure of sperm to electromagnetic radiation does not account for the distance and material, including biologic tissues, that separate a cell phone transceiver and sperm during common use. To address a more typical usage scenario, investigators have used epidemiologic data to gauge potential in vivo effects. In one questionnaire-based study of Norwegian sailors exposed to high-power electromagnetic fields in a military environment, researchers noted a significant linear relationship between increasing exposure and reported infertility (Baste et al, 2008). It is interesting to note that the offspring's sex ratio at birth also revealed a linear relationship, with a decreasing ratio of boys to girls with higher degrees of exposure to electromagnetic radiation (Baste et al, 2008). Researchers in another epidemiologic study divided men

The agent sulfasalazine prescribed for inflammatory bowel conditions is associated with oligoasthenospermia ([Stein and Hanauer, 2000](#)). If sulfasalazine is substituted with enteric-coated mesalazine, adverse effects on sperm are usually reversible ([Riley et al, 1987](#)). Should oligoasthenospermia be found in a patient prescribed sulfasalazine who has male infertility, substitution with mesalazine should consequently be recommended.

Because colchicine arrests cell division and inhibits cell motility dependent on microtubular function, it was suspected as a spermatotoxic agent ([Haimov-Kochman and Ben-Chetrit, 1998](#)). However, its actual role in male reproductive dysfunction is unclear.

In animal studies, the phosphodiesterase type 5 inhibitor sildenafil was observed to induce a premature acrosome reaction and to impair fertilization and early embryo development ([Glenn et al, 2007, 2009](#)). Sildenafil was also associated with an increase in sperm motility, whereas tadalafil was noted to decrease sperm

motility ([Glenn et al, 2007](#); [Mostafa, 2007](#); [Pomara et al, 2007](#)). Investigators observed vardenafil to increase motility and possibly sperm concentration ([Rago et al, 2012](#)). It is unclear whether these effects have significance in actual clinical use.

Researchers have investigated a large number of potential male reproductive environmental toxicants. A very concerning analysis projected that sperm counts declined between 1938 and 1991 (Carlsen et al, 1992). Whereas commentators noted a number of sources of error and bias in that analysis, the report spawned several investigations into an environmental basis for the putative cause of this phenomenon (Carlsen et al, 1992; Jørgensen et al, 2001; Fisch, 2008). One hypothesis explaining this observation was that an increase in pollutants with estrogenic activity was at fault (Carlsen et al, 1992). If that were the case, it would be expected that naturally occurring estrogenic substances should interfere with spermatogenesis. However, the limited data to date support that phytoestrogens, or plant compounds with estrogenic properties, do not display significant negative effects on male reproductive potential (Fraser et al, 2006; Hamilton-Reeves et al, 2010; Messina, 2010). Hinting at a more nuanced relationship, data correlated urine levels of the potent industrial endocrine disruptor bisphenol A and decreased sperm concentration and total sperm count, implying that environmental estrogens may play a role in hampering male reproductive potential (Li et al, 2011). Congruent with these observations, maternal beef consumption was correlated with decreased sperm concentration in the mothers' adult sons, with estrogenic xenobiotics as a possible causative mechanism (Swan et al, 2007).

Evidence supports insecticide and pesticide exposure as male reproductive toxicants. Investigators observed an association of increased DNA damage with urinary metabolites of the insecticides carbaryl and chlorpyrifos (Meeker et al, 2004). In a model system, researchers exposed human fetal testes to the insecticide and endocrine disruptor dieldrin and noted a variety of Leydig cell

dysfunctional effects, including reduced testosterone secretion and LH receptor and steroid regulatory protein concentrations (Fowler et al, 2007). Suggesting that a man consume locally grown produce to avoid ill effects of pesticides may not be in his best interest. In one study, men consuming locally produced vegetables had lower serum free testosterone, LH, and sperm concentration and normal sperm morphology (Dhooge et al, 2007).

Regarding metal and metalloid exposure, various reports suggest an array of potential male reproductive toxicities. **The heavy metal lead was associated with increased morphologic abnormalities and decreased metrics of DNA quality in sperm** (Hsu et al, 2009). These negative effects of lead on sperm DNA appear to be potentiated by cigarette smoking (Hsu et al, 2009). In one study, molybdenum was associated with a 37% reduction in circulating testosterone levels (Meeker et al, 2010). Environmental and workplace exposure to the metalloid boron was associated with decreased ratio of sperm bearing a Y chromosome to those with an X chromosome (Robbins et al, 2008).

Air pollution may also serve as a male reproductive toxin. Researchers observed an association of particulate air pollution with reduced sperm motility (Hammoud et al, 2010a). Exposure to episodes of high air pollution was also associated with increased sperm DNA fragmentation (Rubes et al, 2005). An animal model demonstrated a decrease in the secondary sex ratio with increased air pollution (Lichtenfels et al, 2007). The authors argued that as litter sizes were similar in exposed and nonexposed animals, the most likely explanation was alteration in the ratio of Y- and X-bearing sperm (Lichtenfels et al, 2007).

into four groups based on cell phone talking time: no use; less than 2 hours per day; 2 to 4 hours per day; and more than 4 hours per day (Agarwal et al, 2008b). The investigators observed that semen analyses in the four groups of increasing cell phone use revealed a linear decrease in sperm count, motility, viability, and normal morphology (Agarwal et al, 2008b).

Infections and Inflammation

In the *TICS* mnemonic, *I* stands for infectious and inflammatory disease leading to male reproductive dysfunction. Infections of the testis, epididymis, prostate, and urethra may lead to male infertility through anatomic and functional means (Kasturi et al, 2009). Common organisms affecting the prostate include *Escherichia coli*, *Pseudomonas aeruginosa*, and *Klebsiella*, *Proteus*, and *Enterococcus* species (Kasturi et al, 2009). Typical epididymal organisms include *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, and *E. coli* (Kasturi et al, 2009). Infectious urethral organisms in the context of impaired male reproduction include *N. gonorrhoeae*, *C. trachomatis*, *Mycoplasma* species, and *Trichomonas vaginalis* (Kasturi et al, 2009). Although relatively infrequently encountered, infections of the testis may include the Rubulavirus mumps, Coxsackievirus B, *N. gonorrhoeae*, *C. trachomatis*, *E. coli*, *P. aeruginosa*, and *Klebsiella*, *Staphylococcus*, and *Streptococcus* species (Kasturi et al, 2009). Mumps orchitis is typically so painful and bizarre to the person so affected that even at a very young age, a boy with mumps traveling into his testis is unlikely to forget the event. Infrequently encountered in modern industrialized nations, *Mycobacterium tuberculosis* may affect any reproductive organ and cause scarring of the vas deferens and epididymis (Niederberger, 2011).

Infectious consequences may be anatomic, such as urethral infection leading to stricture, or functional, impairing sperm (Kasturi et al, 2009). Functional alterations may derive from direct effects of the infectious organism on sperm or through induction of immunologic responses in any male reproductive organ, leading to sperm dysfunction (La Vignera et al, 2011). As an example of direct effects, investigators observed that incubating sperm with increasing concentrations of *C. trachomatis* serovar E elementary bodies was associated with degradation of sperm DNA in a time-dependent manner (Satta et al, 2005). Although *in vitro* laboratory experiments have also demonstrated a negative effect of *E. coli* on sperm, the majority of bacteria including *E. coli* have limited or no effects on sperm motility *in vivo* (Diemer et al, 2003; Lackner et al, 2006). Whereas bacteria may coexist with sperm without significant pathologic consequence, sexually transmitted organisms may play a more virulent role (Bezold et al, 2007). The differential effects on sperm of common bacteria and sexually transmitted infectious agents remain far from clear.

Viruses proffer a potentially unique negative direct effect on sperm by integration into a man's genome and vertical transmission through his germ line (La Vignera et al, 2011). Although viral nucleic material appears to be present in the seminal plasma, neither hepatitis C nor human immunodeficiency virus appear to be correlated with a direct negative effect on sperm function (Garrido et al, 2005). Human papillomavirus was associated with impairment of bulk seminal parameters, and *in vitro* treatment of sperm in the laboratory with heparinase III appeared to diminish viral load without significantly altering functional semen parameters (Garolla et al, 2012).

Researchers have studied a wide variety of indirect negative effects of infection on sperm including through leukocytosis, ROSs, interleukins 1, 6, and 8, interferon- γ , macrophage migration inhibitory factor, tumor necrosis factor- α , epididymal macrophages, and dendritic cells (La Vignera et al, 2011). It is logical that any part of the immune system may lose self-recognition of sperm or in the presence of an active infection overwhelm sperm defenses.

Evidence suggests that noninfectious or postinfectious inflammatory processes of the prostate may lead to sperm alterations and male infertility, but the degree to which inflammation alters male reproductive potential beyond what infection imparts remains unknown (Schoor, 2002; Wagenlehner et al, 2008; Ausmees et al,

2013). One putative mechanism by which nonbacterial prostatitis may lead to male infertility is through seminal leukocytosis or pyospermia and the release of ROSs resulting in sperm damage (Schoor, 2002). Other possible means of sperm dysfunction via prostatic inflammation include generation of antisperm antibodies and biochemical alterations in prostatic ions such as zinc, magnesium, calcium, or selenium (Schoor, 2002). Prostatitis may itself damage sperm by inducing ROSs without leukocytosis as an intermediary (Pasqualotto et al, 2000; Schoor, 2002).

Childhood Diseases

The *C* in *TICS* stands for childhood diseases. Maladies of early development include anatomic maldevelopment leading to obstruction or misdirection of the male gamete as it traverses the journey from the testis to the female reproductive tract and disorders that lead to disturbed sperm production or to conditions that damage mature sperm.

Pediatric Surgery

Hydroceles and hernias repaired during childhood are associated with a low but discrete incidence of complications causing vasal obstruction (Lao et al, 2012). In one large series, the rate of testis atrophy after pediatric inguinal hernia was 0.3% (Ein et al, 2006). As hernias repaired during adolescence often include surgical mesh, vasal occlusion as a result of inflammation associated with this material should be considered in an infertile man with such a procedure in his surgical history (Shin et al, 2005; Hallén et al, 2011, 2012; Lao et al, 2012; Tekatli et al, 2012). Other surgical procedures during childhood may also affect future reproductive status. In earlier series, investigators associated scarring from posterior urethral valve ablation with male reproductive dysfunction, but in more recent series, fertility complications with urethral valve surgery are rarely observed (Caione and Nappo, 2011). Older procedures for restoring bladder neck anatomy in children were associated with retrograde ejaculation, but these surgeries are rarely performed today (Sigman et al, 2009).

Testis Torsion

For males 25 years and younger, testis torsion is more than three times more common than testis cancer, with an estimated incidence of 4.5 cases per 100,000 per year (Mansbach et al, 2005; Mellick, 2012). It is interesting to note that contralateral testicular biopsy findings are abnormal in 57% to 88% of males when torsion occurs, which suggests either that unnoticed torsion is damaging the testis before torsion becomes clinically evident or that some underlying pathology is present that manifests both as abnormal scrotal anatomy and as spermatogenic dysfunction (Visser and Heyns, 2003). Approximately half of men with torsion will develop adverse spermatogenic effects (Visser and Heyns, 2003). Overall after torsion, 36% to 39% of men will have sperm concentrations below 20 million/mL (Visser and Heyns, 2003). Because torsion is a traumatic event that disrupts intratesticular architecture including the tight junctions between the Sertoli cells that comprise the blood-testis barrier, it is unsurprising that up to 11% of men will develop antisperm antibodies after torsion (Visser and Heyns, 2003).

Cryptorchidism

As described elsewhere in this text, during the fifth week of gestation, cells destined to become gonads arise in the posterior abdominal wall of the developing embryo (Lewis and Kaplan, 2009). A complex set of highly orchestrated sequenced events occurs, including differentiation of the various testis cell types, organization into what will ultimately become histologic compartments within the testicle, and development of the outer container of the testis and its connection to the distal organs where sperm will be ultimately routed (Lewis and Kaplan, 2009). The most overt anatomic

change is migration of germ cells from the posterior abdominal wall toward the nascent inguinal canals and eventually into the scrotum, resulting in an extra-abdominal localization of the male gonads (Lewis and Kaplan, 2009). This process does not conclude until the third trimester (Lewis and Kaplan, 2009). Researchers have identified multiple regulatory triggers in animal models that direct descent of the testis, including the insulin-like 3 (*INSL3*) gene, the relaxin/insulin-like family peptide receptor 2 (*LGRF8*) gene, antimüllerian hormone (AMH), and members of the *HOX* gene family such as *HOX10* (Hughes and Acerini, 2008; Lewis and Kaplan, 2009). Dysfunction of certain of these genes may result primarily in arresting the mechanical journey of the germ cells, whereas aberrant expression of others may be involved in the processes of both spermatogenesis and descent, causing infertility in ways beyond the thermal toxicity to which undescended testes are subject in later reproductive life. **Androgens are required to induce regression of the cranial suspensory ligament during the fourth month of gestation to allow descent of the testis** (Hughes and Acerini, 2008; Lewis and Kaplan, 2009). Failure of any of these processes impedes descent of the testis into the scrotum, resulting in cryptorchidism, which is widely known to be associated with impaired reproductive potential in later life (Sigman et al, 2009).

Undescended testes occur in up to 4% of newborn boys at term (Barthold and González, 2003). The prevalence of cryptorchid testes decreases to less than 1.5% by 1 year of age (Barthold and González, 2003; Chung and Brock, 2011). Cryptorchidism concordance analysis in twins and siblings indicates a pattern of maternal inheritance, but also suggests that the intrauterine environment plays an important role (Jensen et al, 2010). In most series, the incidence of unilateral cryptorchidism is usually around twice that of bilateral undescended testes (Barthold and González, 2003). The distinction is important, because prognosis is related to whether cryptorchidism is unilateral or bilateral. The reproductive prognosis in later life is similar in men with no history of cryptorchidism and in those with a unilateral undescended testis who underwent orchidopexy as a child, regardless of age at surgery or the size of the undescended testis (Lee et al, 2001; Miller et al, 2001). In one large epidemiologic study of men who had orchidopexy during childhood, successful rates for those attempting paternity with a history of surgically treated unilateral cryptorchidism were 96% compared with a control population, but only 70% for those who had bilateral cryptorchidism (Lee, 2005). In that study, men with bilateral cryptorchidism had levels of the Sertoli cell product and marker of spermatogenesis inhibin B that were nearly one third of the levels in controls, compared with men with unilateral undescended testes repaired in childhood, who had inhibin B levels approximately two thirds that of controls (Lee, 2005). Differences in testosterone concentrations were less than those of inhibin B, arguing that fertility impairment caused by cryptorchidism is less based in Leydig cell steroidogenesis than in dysfunction of the seminiferous epithelium (Lee, 2005). Congruent with the identified differences in inhibin B between men with neither, one, or both testes undescended, researchers observed that sperm density on semen analysis is lower in men who had surgical repair of bilateral cryptorchidism than in those with a unilateral undescended testis, which in turn is lower than in men with normally descended testes (Lee, 1993; Lee and Coughlin, 2001; Moretti et al, 2007). With transmission electron microscopy, investigators also found a greater number of ultrastructural defects in men who had cryptorchidism surgically treated as a child compared with controls, and sperm from men with bilateral undescended testes had more defects than from those with unilateral disease (Moretti et al, 2007).

Conclusive data associating the timing of orchidopexy with reproductive outcomes in later life remain elusive. It is widely recognized that surgical correction of undescended testes after puberty likely has minimal effect on bulk semen analysis parameters (Grasso et al, 1991). However, the age before puberty at which orchidopexy results in optimal effect in reproductive potential has not been definitively established. Regression analysis demonstrated

that serum testosterone concentrations in men were negatively correlated to increasing age at orchidopexy, indicating that Leydig cell function is better spared by earlier age of surgical correction for cryptorchidism (Lee, 2005). Conventional wisdom contended that full germ cell development is arrested and remains quiescent before puberty, implying that orchidopexy performed at any earlier age would have similar outcomes. However, maturational alterations may occur in the hypothalamic, pituitary, and testicular endocrine axis much earlier than adolescence (Hadziselimovic, 2002). Likewise, a transition from the spermatogonial cell types of the fetal germ cell reservoir to that of the adult occurs at a very early age (Hadziselimovic, 2002).

Studies of men undergoing testis sperm extraction with the intent for use in ICSI and who had cryptorchidism and orchidopexy at an earlier time offer some information about the optimal timing of surgical correction of undescended testes, although results are conflicting. In an early study of 30 azoospermic men who had bilateral cryptorchidism, no correlation was found between the age at bilateral orchidopexy and the rate of successful surgical sperm retrieval, which was 73% overall (Negri et al, 2003). In a later study of 42 azoospermic men in whom all but two had bilateral cryptorchidism, no significant differences in surgical sperm retrieval rate were observed comparing men who had orchidopexy up to 10 years of age (61.9%) and men whose testes were brought into the scrotum after 10 years of age (57.1%) (Wiser et al, 2009). However, in an early study of 38 azoospermic men with 30 having had bilateral cryptorchidism, the successful surgical retrieval of sperm in 94% for men who had orchidopexy up to 10 years, 43% for 11 to 20 years, and 44% for older than 20 years, was statistically different at the selected threshold of 10 years ($P < .01$) (Raman and Schlegel, 2003). Congruent with these results, in 79 azoospermic men, 62% having had bilateral orchidopexy and 20.3% having had unilateral orchidopexy (with 17.7% unknown), ROC curve analysis revealed age at orchidopexy to have the second greatest area under the curve (AUC) after testosterone in discriminating successful surgical sperm retrieval (Vernaev et al, 2004). **It consequently appears prudent to recommend orchidopexy before 10 years of age from a reproductive perspective, recognizing that cryptorchid boys who pass that threshold still may have sperm surgically retrieved for use in ICSI later in life.**

Testes that change in position after descent and those that are nearly but not fully descended present special challenges in assessing potential alterations in reproductive potential. Numerous reports clearly document testes as being descended that are later observed to have ascended to varying degrees (Gracia et al, 1997; Barthold and González, 2003). Whereas most appear to ascend to a location distal to the inguinal canal, clinicians have reported ascent as high as to an intra-abdominal position (Gracia et al, 1997; Barthold and González, 2003). Unfortunately, the fertility potential for these patients has not yet been systematically studied, and their reproductive prognosis must be considered unknown at present. For men with retractile testes, limited data suggest that although sperm are often observed in the ejaculate in a man, sperm density is lower than would be expected in a man with normal fertility, approaching that of men with a history of cryptorchidism (Caroppo et al, 2005).

Testicular Dysgenesis Hypothesis

Please see the Expert Consult website for details.

Genetics

What is currently known of the genetic basis of male infertility will be discussed systematically later in this chapter. A good reproductive history should include whether any blood relatives experienced difficulty conceiving offspring. The evaluating physician should also inquire as to the presence in the patient's family of genetic syndromes known to be related to reproductive dysfunction such as cystic fibrosis and other entities detailed in the latter part of this chapter (Anguiano et al, 1992).

Investigators have noted an increase in the incidence of testis cancer and genitourinary abnormalities such as hypospadias and cryptorchidism and a concomitant decrease in seminal bulk parameters in general over time (Carlsen et al, 1992). The actual existence of each effect can be individually debated, and internal covariates are difficult to statistically assess (Akre and Richiardi, 2009; Thorup et al, 2010). However, the fact that sufficient evidence exists to posit the correlation of possible adverse male reproductive epidemiologic trends begs the question of what would be potentially responsible for a common “testicular dysgenesis syndrome” that would lead to multiple manifestations in reproductive dysfunction, cancer, and anatomic birth defects (Skakkebaek et al, 2001). Researchers have reported a paternal concordance, with fathers of boys with hypospadias having an increased probability of decreased sperm density

and of also having hypospadias (Asklund et al, 2007). This observation indicates a potential genetic component to a possible testicular dysgenesis syndrome. Investigators have also correlated environmental estrogenic compounds such as dichlorodiphenyltrichloroethylene, polychlorinated biphenyls, and dibutylphthalate exposure to cryptorchidism, suggesting that environmental toxicants may lead to testicular maldevelopment and potentially other reproductive system impairments (Brucker-Davis et al, 2008). These observations and conjectures must be tempered by the difficulties inherent in assessing male reproductive epidemiologic data (Akre and Richiardi, 2009; Thorup et al, 2010). However, it would seem prudent to continue to investigate whether such a testicular dysgenesis syndrome exists, and if so, what its root causes may be to ameliorate it.

Sexual History

The S in *TICS* is for the sexual history. Although it may seem intuitive that a couple would engage in a sufficient frequency of intercourse when attempting to conceive, lifestyle or proclivities may intervene and interfere. As discussed previously in this chapter, optimum timing for intercourse appears to be daily around the time of ovulation (Scarpa et al, 2007). Some women accurately predict the periovulatory period by symptoms, the so-called mittelschmerz (O'Herlihy et al, 1980). However, many women mistake bodily sensations as ovulation, and symptoms alone cannot reliably be used to assess optimal timing for intercourse. **Because ovulation is detectable by basal body temperature or home hormonal kits after it has occurred, a couple should be encouraged if possible to record the day of ovulation for two or three menstrual cycles, and begin daily intercourse several days before the earliest recorded day.** Such a method is impractical for women with advanced age, as it delays potential reproductive therapies. In the setting of advanced maternal age, more aggressive strategies in collaboration with the female fertility specialist should be considered.

Lubricants commonly used during sexual activity such as K-Y Jelly, Keri Lotion, Astroglide, and others are associated with impaired sperm motility (Sigman et al, 2009). Saliva should also be considered toxic to sperm (Sigman et al, 2009). Researchers incubated a variety of lubricants with sperm and observed that the isotonic preparation Pre-Seed did not result in a significant decrease in sperm motility or chromatin integrity as assessed by an acridine orange-based sperm chromatin structure assay (Agarwal et al, 2008a). In that study, FemGlide, Replens, and Astroglide lubricants resulted in a significant decrease in motility, and FemGlide and K-Y Jelly resulted in a significant decline in sperm chromatin quality (Agarwal et al, 2008a). Laboratory investigators have also provided evidence that use of Pre-Seed during semen collection for analysis does not affect assessment of bulk seminal parameters, sperm membrane functional integrity, levels of ROSs, total antioxidant capacity (TAC), and DNA integrity (Agarwal et al, 2013).

The urologist should inquire about erectile function, because obviously if intercourse is impeded or impossible, sperm will not be deposited successfully in the vaginal vault near the cervical os. The physiology, evaluation, and treatment of erectile dysfunction are discussed extensively elsewhere in this text.

The psychological weight of having a diagnosis of infertility and the stress of the therapy are significant (Schanz et al, 2005; Volgsten et al, 2008). One metric of whether infertility is exerting an adverse psychological effect on the male is frequency of intercourse, which may be altered in up to half of men being treated for infertility and is associated with libido and sexual satisfaction (Ramezanzadeh et al, 2006). A revealing question for a man undergoing male reproductive evaluation is whether the frequency of coitus has changed during the process.

Men and women adapt to the stress of infertility in different ways with different coping mechanisms (Peterson et al, 2006). Men tend to distance themselves and problem solve, whereas women are more likely to seek social support (Peterson et al, 2006). Men and women may consequently interpret their partner's natural adaptive strategy as problematic when in fact it is simply a different means of coping. **A common misconception is that men conflate fertility with masculinity, which in fact happens only infrequently (Fisher et al, 2010).**

Stress itself may impair semen quality, creating a vicious circle for men experiencing infertility and its related psychological distress (Gollenberg et al, 2010). Fortunately, evidence suggests that once men have entered into reproductive medical therapy including IVF with their partners, the diagnosis of male infertility does not disturb psychological well-being and well-adjusted relationships (Holter et al, 2007). The clinician treating male reproductive dysfunction should consider referral to a qualified psychologist to ease the transition from the fearsome diagnosis of infertility to the many effective therapies that are available. If the discussion is couched in terms of problem solving, many men are very willing to engage in psychological counseling.

KEY POINTS: MALE REPRODUCTIVE HISTORY

- The most important determinant of a couple's reproductive potential is maternal age.
- Many conditions may affect male reproductive function. The examining physician may organize the male reproductive history into toxicants, infectious processes, childhood conditions, and sexual history.

PHYSICAL EXAMINATION

General Physical Examination

Because male infertility may be related to many systemic and genetic conditions, the general physical examination often yields clues as to the source of reproductive dysfunction. Male and female faces are morphologically distinct, and female facial characteristics alert the examining physician to potential sex chromosomal and androgenization disorders (Veleminská et al, 2012). Alterations in secondary sexual characteristics such as facial, truncal, axillary, and pubic hair suggest inadequate androgenization (Sigman et al, 2009). If androgenization is significantly impaired through puberty, a high-pitched voice may result (Sokol, 2009). An overabundance of endogenous or therapeutically induced estradiol may lead to gynecomastia (Sigman et al, 2009). If testosterone production during puberty is so low that closure of the epiphyses of the long bones of the extremities fails to occur, typical body morphology will include an arm span 5 cm longer than the patient's height and a lower body segment as defined by pubic-to-heel distance more than 5 cm longer than the upper body segment as measured from the crown to the pubis (Sokol, 2009).

With the lack of virilization at the anticipated time of puberty, Klinefelter syndrome is classically detailed in textbooks as resulting in gynecomastia, a eunuchoid appearance, and tall height for age (Oates and Lamb, 2009). However, it should be noted that many men with a 47,XXY karyotype do not display the typical body morphology and habitus so described.

Obesity should be noted because substantial evidence associates it with male reproductive dysfunction. **It is well established that obese men have elevated estradiol as a result of peripheral conversion from testosterone by an overabundance of adipose cells that contain the enzyme aromatase (Hammoud et al, 2006; Aggerholm et al, 2008; Chavarro et al, 2010; Hammoud et al, 2010b; Hofny et al, 2010).** A TTTA aromatase polymorphism appears to be particularly related to increasing estradiol with increasing body mass, and those with the polymorphism are most likely to experience decreasing estradiol when they lose weight (Hammoud et al, 2010b). **Serum testosterone is also well known to be lower in obese men (Hammoud et al, 2006).** Four main causes are hypothesized: negative feedback of estradiol on the hypothalamic-pituitary axis resulting in decreased LH release; increased leptin; insulin resistance; and sleep apnea (Hammoud et al, 2006; Hofny et al, 2010). It should be noted that although some studies correlate increasing obesity with decreased LH, others do not, and the mechanism of reduced testosterone in obese men may be unrelated to gonadotropins (Hammoud et al, 2006; Aggerholm et al, 2008; Pauli et al, 2008; Hofny et al, 2010; Paasch et al, 2010; Teerds et al, 2011).

SHBG is typically reduced in obese men, in general ascribed to increased circulating insulin in obesity (Hammoud et al, 2006; 2008; Pauli et al, 2008; Teerds et al, 2011). The consequence of lowered SHBG is that bioavailable testosterone may be greater than what total testosterone predicts, and an obese man may be more androgenized than expected on superficial laboratory assessment.

Researchers observed an inverse correlation between serum inhibin B concentrations and body mass index (BMI) in men but not prepubertal boys (Winters et al, 2006). The association between decreasing inhibin B and increasing obesity in men potentially indicates decreased Sertoli cell number, and that the relationship is

not seen before puberty suggests that obesity exerts its negative effect on Sertoli cells during puberty (Winters et al, 2006).

Although these kinds of studies have associated obesity with altered male hormones that consequently result in infertility through an endocrine effect, researchers have also implicated increased BMI with decreased paternity in investigations that suggest that the adverse effects of obesity on male reproduction may be independent of the endocrine system (Pauli et al, 2008; Stewart et al, 2009). Some evidence suggests that only extreme obesity negatively affects male fertility through an endocrine pathway (Chavarro et al, 2010). Other published studies have observed a relationship only between sperm motility and BMI, but not an association with sperm concentration, suggesting that obesity may primarily interfere with epididymal function that imparts motility to sperm (Martini et al, 2010). Some studies indicate that obesity may degrade sperm DNA integrity and mitochondrial activity, whether through the final common pathway of the endocrine system or another hormonal-independent mechanism (Fariello, et al, 2012a). Although this evidence suggests that the endocrine system is a probable target for impairment of reproductive effects in the male, it is likely that the full elucidation of the means by which excess adiposity exerts its effects on male reproduction is beyond such a singular process.

Male Reproductive Physical Examination

Fortunately for the examining physician, much of the male reproductive system is located outside of the body cavity, where it can be easily palpated. Because much of the male reproductive physical examination is most effectively performed with the patient standing, it is important to put the patient both at ease and before a low examining table or chair, as some men will develop syncope during palpation of the scrotum. Asking a man about his work often serves to distract him from the male genital examination (Niederberger, 2011).

If the partner of the patient is present during the history, she may relate valuable information. However, the patient may also feel reluctant to divulge specific facts of reproductive significance before his partner, and the physical examination presents an opportunity to tactfully ask her to leave the room to allow the man time to discuss issues with his physician privately (Niederberger, 2011).

Examining the Scrotum

Visual observation of the scrotum may be revealing. One or both sides may be hypoplastic, indicating an absence of the scrotal contents since birth (Niederberger, 2011). One side may be substantially larger than the other, suggesting a reactive hydrocele or tumor. A varicocele may be so large as to be visible. Finally, proximity to the thighs in a large or obese male may indicate an insufficient difference between intrascrotal and body temperature.

Examining the Testis and Epididymis

The examiner first palpates the testis and epididymis through the scrotum, noting any abnormalities. The epididymis is typically difficult to appreciate; if it is easily palpated, it is likely engorged, which suggests obstruction. Segmentation of the epididymis is also worthwhile to note: If the portion near the upper pole is easy to discern but the lower pole is not, wolffian ductal development may have been incomplete (Lewis and Kaplan, 2009).

Testis size is well established to correlate with sperm production and is consequently an important assessment in the physical examination of the infertile male (Takahara et al, 1987; Bujan et al, 1989). The size of the testis may be assessed by calipers often referred to as the *Seager orchidometer* (Fig. 24-1) (Niederberger, 2011). The long axis of the testis is gently grasped between the jaws of the calipers, and a measurement of 4.6 cm or less is associated with spermatogenic impairment (Schoor et al, 2001). A second method to ascertain testis size is to compare the examiner's palpation findings with a string of ellipsoids of increasing size with marked

Figure 24-1. Caliper (Seager) orchidometer.

Figure 24-2. Prader orchidometer. (Courtesy Erler Zimmer GmbH and Co. KG, Germany.)

volumes as shown in Figure 24-2 (Niederberger, 2011). A volume of 20 mL or less is considered low (Sigman et al, 2009). Finally, testis volume may be more directly measured by ultrasonography of the scrotum (Sakamoto et al, 2007a, 2007b; Abdulwahed et al, 2013). However, it is unclear the degree to which the incremental increase in accuracy that testis ultrasound adds to that obtained by the caliper or Prader orchidometer translates to clinically useful information (Sakamoto et al, 2007a).

Examining the Spermatic Cord

Palpation of the spermatic cord yields two features of reproductive significance: whether the vas deferens is palpable, and whether a varicocele is present. The vas is a firm cordlike structure differentiated from vasculature within the spermatic cord by the compressibility of the vessels. Because the veins within the cord may be mistaken for the vas on manual examination of the upper scrotum, absence of the vas can be a difficult physical sign to identify. For the clinician with experience in vasectomy, one useful method of identifying whether the structure is absent is to search for the vas as if performing the first step of a vasectomy, bringing it to the surface of the skin. If what is presumed to be the vas disappears from the examiner's fingers three times, the clinician can be

confident that the vas is absent. This pearl is referred to as *Meacham's maxim* after Randall Meacham, who described the technique (Niederberger, 2011).

Unilateral absence of the vas deferens suggests the possibility of a complete lack of wolffian ductal development on that side, including renal agenesis. In such patients, a renal ultrasound may be considered to investigate whether the patient has a solitary kidney (Niederberger, 2011). If both vasa are absent, the man has a high likelihood of a cystic fibrosis gene mutation (Anguiano et al, 1992). In such patients, laboratory genetic assessment of the cystic fibrosis transmembrane conductance regulator gene sequence is indicated (Lyon and Miller, 2003; Bombieri et al, 2011). Because investigators have noted renal agenesis in 11% of men with congenital bilateral absence of the vas deferens (CBAVD), renal ultrasound may also be considered to investigate whether a solitary kidney is present (Schlegel et al, 1996).

In addition to assessing the presence, absence, and continuity of the vas deferens, the clinician examining the upper scrotum views its surface to determine if a plexus of varicose veins arising from the spermatic cord is visible and then gently palpates to identify whether a varicocele may be felt. Although sporadic reports before 1955 described cases in which surgery on varicocele yielded evidence of improved reproductive potential, W. Selby Tulloch was the first to systematically report a series of cases of infertile men undergoing high ligation of a varicocele and subsequent improvement in sperm counts (Tulloch, 1955). Lawrence Dubin and Richard Amelar studied varicocele and its treatment in larger series and broadly educated urologic surgeons on its pathology and the merits of therapy (Dubin and Amelar, 1975; Nagler and Grotas, 2009).

The varicocele is the most commonly encountered nonductal surgically addressable pathologic entity potentially affecting male reproductive potential (Nagler and Grotas, 2009). In general, incidence estimates in the general population range from one fifth to one sixth, whereas most studies suggest the incidence of varicocele in infertile males to be between one third and one half (Pryor and Howards, 1987; Fretz and Sandlow, 2002; Nagler and Grotas, 2009). That not all men with varicocele are infertile remains one of the most perplexing problems in male reproductive medicine today; the choice of therapy for a particular man with a varicocele is challenging.

Clinical studies of varicocele have used multiple grading systems to describe the severity of the entity, further complicating the task of the evaluating physician (Nagler and Grotas, 2009; Williams, 2011). Most systems use three or four grades, usually with the first being a varicocele that cannot be palpated but can be detected only by radiographic evaluation, typically ultrasound (Nagler and Grotas, 2009; Williams, 2011). Some systems differentiate varicoceles that can be palpated only during the Valsalva maneuver (Nagler and Grotas, 2009). Because the majority of studies concur that treatment of subclinical varicoceles does not significantly improve male reproductive potential, a sensible grading system would include these entities, which are best left untreated, to differentiate them from those that ought to be addressed with therapy (Niederberger, 2011). Likewise, the difference between varicoceles that can be seen and those that can only be felt is clinically obvious, and a reasonable grading system would differentiate the two (Niederberger, 2011). As the clinical significance of those varicoceles that can only be appreciated with the Valsalva maneuver is uncertain, a rational grading system would not include this feature as a major discriminator. Hence, the modern evidence-based clinical grading system for varicocele includes grade I, which is not palpable or visible and can only be detected by radiographic evaluation such as Doppler ultrasound; grade II, which is palpable but not visible; and grade III, a varicocele that is so large as to be visible by the examining physician through the rugae of the scrotum (Niederberger, 2011).

Examining the Phallus

In the typical setting of intercourse, semen must be deposited proximal to the cervical os for optimal chance of reproduction. Consequently, any abnormality of the phallus that may prevent placement

of the semen at that locale should be noted by the examining physician. These abnormalities include phimosis, meatal displacement in hypospadias or epispadias, and significant penile curvature (Niederberger, 2011).

Examining the Prostate and Seminal Vesicles

In general, examination of the prostate and seminal vesicles does not add a significant amount of information to the evaluation of the infertile male, and if the patient is sufficiently apprehensive about digital rectal examination, it may be prudently omitted. Should rectal examination be performed, the clinician notes the size of the prostate, as it may be aplastic or hypoplastic in cases of congenital malformation or significant hypogonadism (Niederberger, 2011). The seminal vesicles cannot typically be palpated; if they are palpable, it is an abnormal finding suggesting engorgement and possible ejaculatory ductal obstruction (Niederberger, 2011).

KEY POINTS: MALE REPRODUCTIVE PHYSICAL EXAMINATION

- Obesity impairs male reproductive potential by endocrine-dependent and endocrine-independent mechanisms.
- Testis size directly reflects spermatogenic mass.
- Unilateral absence of the vas deferens suggests a wolffian ductal anomaly; bilateral absence is associated with mutations in the gene responsible for cystic fibrosis. In both, renal agenesis may result.

LABORATORY EVALUATION OF MALE INFERTILITY

Like other aspects of urology, much can be learned about the condition of male infertility from blood tests, in this case, primarily of the endocrine system. Also similar to other urologic fields, genomic assessment of male reproductive function is a burgeoning area of research and increasing clinical usefulness. However, the laboratory inquiry into male infertility also includes a way of directly appraising the severity of the condition by observing the male gametes in the semen analysis. These three general laboratory assessments comprise the laboratory evaluation of male infertility: the endocrine evaluation, analysis of semen, and genomic assessment.

Endocrine Evaluation

As spermatogenesis is highly dependent on intratesticular testosterone synthesis, it is unsurprising that hypogonadism is associated with male infertility. Testosterone levels in men vary widely, and most investigators use either 280 ng/dL or 300 ng/dL as a threshold for adequate androgenization in a man (Petak et al, 2002; Sokol, 2009). Approximately 45% of men with azoospermia caused by spermatogenic dysfunction are observed to have testosterone less than 300 ng/dL, and serum testosterone below that threshold is found in 43% of men with oligospermia and 35% of men in an infertility clinic with sperm density greater than the threshold of 20 million/mL specified in the fourth edition of the WHO laboratory manual for the examination and processing of human semen (Sussman et al, 2008). Because 90% of men with sperm density of 22 million/mL or less will not have conceived with their partners within 1 year, many with sperm density less than that value are expected to have pathologic reproductive dysfunction, and consequently in approximately one third it is likely related to endocrinopathy (WHO, 2010). Androgenization should therefore be assessed by laboratory evaluation in all men presenting for infertility including those in whom sperm density is greater than 20 million/mL. An upper limit of sperm density has not been established above which endocrine dysfunction is unlikely to be discovered; clinicians may reasonably use the 50th percentile value

in the fourth edition of the WHO manual of 73 million/mL with time to pregnancy within 1 year as a guide, suggesting that a full endocrine evaluation is not necessary (WHO, 2010).

Testosterone circulates in three main forms: tightly bound to SHBG; loosely bound to protein, primarily albumin; and unbound or free (Matsumoto and Bremner, 2011). The forms inducing cellular activity are free and loosely bound, together comprising what is referred to as *bioavailable testosterone* (Matsumoto and Bremner, 2011). In the healthy man, 30% to 44% of circulating testosterone is bound to SHBG, 54% to 68% is loosely bound to albumin, and 0.5% to 3.0% is unbound (Matsumoto and Bremner, 2011). Using a threshold of 300 ng/dL for testosterone and the lower limit of 54.5% for percent bioavailable testosterone, a reasonable lower limit for the concentration of bioavailable testosterone would consequently be 164 ng/dL.

SHBG is altered in a variety of medical conditions and states such as obesity and aging (Box 24-1) (Bhasin et al, 2010). The clinician cannot rely on total testosterone to gauge bioavailable testosterone, and because obtaining an accurate laboratory assessment of free testosterone can be difficult, a practical method of determining bioavailable testosterone is to calculate it from total testosterone, SHBG, and albumin (Vermeulen et al, 1999). Internet-based and smartphone calculators are available; as of this writing, the International Society for the Study of the Aging Male hosts a calculator at www.issam.ch/freetesto.htm, and a calculator for iOS devices may be found at <http://itunes.apple.com/us/app/bioavailable-testosterone/id308770722>.

In young, healthy men, total serum testosterone exhibits a circadian rhythm, with a peak in the early morning and trough levels in the late afternoon (Plymate et al, 1989). SHBG displays an opposing circadian rhythm in men of all ages, with a peak in the late afternoon and a trough in the early morning (Plymate et al, 1989). Consequently, bioavailable testosterone demonstrates a marked circadian rhythm in young, healthy men, with a peak in the early morning and trough in the late afternoon (Plymate et al, 1989). In older men, total testosterone and its circadian rhythm are attenuated, and the circadian rhythm and concentration of bioavailable testosterone are substantially diminished (Plymate et al, 1989). To standardize sampling of total and bioavailable testosterone in all men, assays are typically performed in the morning, although the necessity of such timing is more important in younger men.

In the case of hypoandrogenism, a pituitary or testicular source is identified by assessing LH (Niederberger, 2011). If testicular Leydig cell dysfunction is the cause, LH is elevated to varying

degrees (Niederberger, 2011). In the case of pituitary dysfunction, LH is decreased (Niederberger, 2011). The clinician may assess LH after total or bioavailable testosterone returns with a low value, or, for efficiency, both assays may be performed simultaneously. Because testosterone and LH are released in a pulsatile fashion, borderline results may be investigated further by obtaining three morning samples at 20-minute intervals (Sokol, 2009). Historically, clinicians pooled these samples for a single measure, but three separate assay results may be determined and arithmetically averaged.

The Sertoli cell products inhibin B and activin regulate pituitary follicle-stimulating hormone (FSH) by respectively inhibiting and stimulating its release (Caroppo, 2011). Because the Sertoli cells are regulated by robust paracrine interaction with germ cells, with depopulation of the latter, inhibin levels decrease and FSH consequently increases (Niederberger, 2011). Clinicians have consequently used FSH as an indirect assessment of germ cell mass, with higher concentrations of FSH indicating increasing germ cell dysfunction and depopulation (Niederberger, 2011). Combined with testis size as measured by caliper orchidometer, FSH is an accurate predictor of whether azoospermia is a result of obstruction or spermatogenic dysfunction: 96% of men with obstructive azoospermia had FSH assay values of 7.6 IU/L or less and testis long axis greater than 4.6 cm, whereas 89% of men with azoospermia caused by spermatogenic dysfunction had FSH values greater than 7.6 IU/L and testis long axis 4.6 cm or less (Schoor et al, 2001). In the case of male reproductive dysfunction in which sperm is present in the ejaculate, the odds ratio of abnormal sperm concentration increased markedly at an FSH value of 4.5 IU/L, suggesting another threshold that the clinician may use to assess male reproductive dysfunction (Gordetsky et al, 2011).

Assays of inhibin B are clinically available, and investigators have investigated whether measuring inhibin B directly is a more accurate assessment of spermatogenic function than the indirect assay of FSH (Kumanov et al, 2006; Muttukrishna et al, 2007; van Beek et al, 2007; Myers et al, 2009; Jørgensen et al, 2010; Grunewald et al, 2013). In general, these studies include analyses of correlation between inhibin B or FSH and sperm parameters or testis parameters measured by physical examination. Many studies observe greater accuracy with measuring inhibin B than with FSH in these correlations, and some data suggest that lower ranges of inhibin B allow improved correlation (Kumanov et al, 2006; van Beek et al, 2007; Myers et al, 2009; Grunewald et al, 2013). However, the incremental improvement in accuracy is typically small, and inhibin and FSH both provide clinically useful markers of spermatogenic function (Myers et al, 2009). The clinician may consequently use either marker based on cost and availability.

Like inhibin B, AMH is a member of the transforming growth factor- β (TGF- β) family synthesized by Sertoli cells, and investigators have studied its use as an assay in assessing spermatogenic function (Fénelich et al, 1999; Fujisawa et al, 2002; Muttukrishna et al, 2007). Although results from pilot studies are encouraging, reported data sets remain small, and use of AMH is considered primarily experimental.

Aromatase enzymes convert cholesterol-based molecules such as testosterone to estrogens and are found in many organ systems including testis, adipose tissue, liver, and brain (Kim et al, 2013). Estradiol is consequently measurable in men, and investigators have proposed that elevated estradiol adversely affects male reproductive potential (Raman and Schlegel, 2002; Gregoriou et al, 2012; Schlegel, 2012). A ratio of total testosterone to estradiol below 10:1 is suggested to indicate reproductive dysfunction (Raman and Schlegel, 2002; Gregoriou et al, 2012; Schlegel, 2012).

The pituitary hormone prolactin is known to inhibit gonadotropins and suppress testosterone production in men, and it may be elevated in pituitary hyperplasia, adenoma, or tumors (Sokol, 2009). Clinically significant disease of the pituitary is typically associated with symptoms such as visual field changes, headache, or erectile dysfunction (Niederberger, 2011). Prolactin assay should be considered when these symptoms accompany male infertility, especially if total or bioavailable testosterone is low. However, the

BOX 24-1 Conditions Associated with Altered Sex Hormone-Binding Globulin (SHBG) Concentrations

CONDITIONS ASSOCIATED WITH DECREASED SHBG

Obesity
Nephrotic syndrome
Hypothyroidism
Glucocorticoids, progestins, and androgenic steroid therapy
Acromegaly
Diabetes mellitus

CONDITIONS ASSOCIATED WITH INCREASED SHBG

Aging
Hepatic cirrhosis and hepatitis
Hyperthyroidism

Human immunodeficiency virus disease

Modified from Bhasin S, Cunningham GR, Hayes FJ, et al. Testosterone therapy in men with androgen deficiency syndromes: an Endocrine Society clinical practice guideline. *J Clin Endocrinol Metab* 2010;95:2536–59.

incidence of clinically significant prolactinoma is very low in infertile males, with only four detected in 1035 men in one large screening study, and prolactin need not be routinely included in the initial endocrine evaluation of an infertile man (Sigman and Jarow, 1997). Prolactin is commonly a labile assay; should it be found to be elevated, repetition of the test is warranted (Niederberger, 2011). Assessment of other pituitary hormones such as thyroid-stimulating hormone, adrenocorticotrophic hormone, or growth hormone is indicated if a space-occupying pituitary lesion is suspected or found on imaging examination (Sokol, 2009). Likewise, should signs of other endocrine disease, such as exophthalmos, striations, moon facies, or facial bony changes, be observed, thyroid hormone, cortisol, or growth hormone assays may be entertained. However, they need not be included in the initial screening evaluation of an infertile man. **A reasonable initial laboratory screen to assess an endocrine basis for male reproductive dysfunction should be performed in the morning and includes total testosterone, SHBG, and albumin to calculate bioavailable testosterone; LH and FSH to gauge pituitary function; and estradiol to evaluate aromatization.**

Men with a history of congenital adrenal hyperplasia (CAH) may develop testicular adrenal rest tumors and infertility later in life (Pierre et al, 2012; Aycan et al, 2013). In these patients, serum 17-hydroxyprogesterone, $\Delta 4$ -androstenedione, renin, and testosterone can be used to assess response to therapy (Pierre et al, 2012).

Evaluation of Semen

Reproduction is a probabilistic system: The more viable sperm that begin their journey in the female reproductive tract, the greater the chance that one will penetrate and fertilize the ovum. In this sense, there is only one definitive result of a semen analysis, and that is the condition in which no sperm are present; only in that case can a man be absolutely considered sterile.

In 1951, the physiologist John MacLeod published the first stringent statistical assessment comparing what could be observed under the light microscope in semen from men who had successfully impregnated their partners versus semen of men who had not done so (MacLeod, 1951). MacLeod applied a descriptive statistical approach, computing cumulative probability histograms for each observable parameter and determining quartiles for each of the two groups of men (MacLeod, 1951). Basic parameters studied included the concentration of sperm, their movement, and their shape (MacLeod, 1951). What is immediately evident from MacLeod's seminal publication is that the histograms for sperm parameters from fertile and infertile men are largely overlapping, meaning that a substantial range of values for any parameter do not discriminate between male fertility and infertility (MacLeod, 1951). MacLeod sensibly approached this problem by considering lower sperm parameter values to be more appropriate thresholds for suggesting male infertility; however, values above these lower thresholds do

not confirm fertility (MacLeod, 1951). This proved to be very difficult to grasp in clinical implementation, and the field of reproductive medicine is rife with the assumption that should a parameter be above a threshold—for example, sperm concentration greater than 20 million/mL—then the man is established to be fertile, which is incorrect. The only conclusion that may be drawn from such a comparison is that should the parameter be lower than the threshold, the man is likely to be infertile; the converse is not necessarily true.

One general approach to the problem of an assay for which the values representing disease and health are overly coincident is to establish two thresholds, beyond which health or disease is probable, and within which no predictive statement can be made. In one study to develop two such sets of thresholds for semen analysis, investigators applied the computational method classification and regression tree (CART) analysis to semen analyses from fertile men and those whose wives were undergoing intrauterine insemination (IUI) and for whom female infertility had been largely excluded (Guzick et al, 2001). As an example, for sperm concentration, 13.5 million/mL was found to be the lower parameter, and 48.0 million/mL was identified as the upper parameter (Guzick et al, 2001). Using these parameters, the clinician would counsel a man whose sperm concentration was less than 13.5 million/mL that he was likely infertile, and one with a concentration greater than 48.0 million/mL that he was likely fertile. Should the man's concentration be greater than 13.5 million/mL and less than 48.0 million/mL, no assessment of fertility potential could be accurately made.

Bulk Semen Parameters and the World Health Organization Criteria

Building on the original work by MacLeod and deriving consensus from a group of experts, WHO established criteria for semen analysis parameters in its laboratory manual for the examination and processing of human semen (Cooper et al, 2010; WHO, 2010; Niederberger, 2011; Murray et al, 2012). For the first four editions of the manual, criteria were set both by expert panel and survey data, and included such thresholds as sperm density of 20 million/mL, which would be judged as a reasonable number below which a man should be considered likely infertile (Cooper et al, 2010; WHO, 2010; Niederberger, 2011; Murray et al, 2012). The problems with such a set of criteria are manifestly evident: fertile men may be found below the thresholds and infertile men above.

The fifth edition of the WHO laboratory manual departed from the previous four by emphasizing the statistical description of the population of men on which it was based (Cooper et al, 2010; WHO, 2010). Values for percentiles of semen parameters from men whose partners became pregnant within 1 year of discontinuation of contraceptives are tabulated, allowing the clinician to compare an infertile patient's results with a fertile cohort (Table 24-2)

TABLE 24-2 Bulk Semen Analysis Parameter Percentiles

PERCENTILE	2.5	95% CI	5	95% CI	10	25	50	75	90	95	97.5
Semen volume (mL)	1.2	(1.0-1.3)	1.5	(1.4-1.7)	2	2.7	3.7	4.8	6	6.8	7
Sperm concentration (million/mL)	9	(8-11)	15	(12-16)	22	41	73	116	169	213	259
Total number (million/ejaculate)	23	(18-29)	39	(33-46)	69	142	255	422	647	802	928
Total motility (%)	34	(33-37)	40	(38-42)	45	53	61	69	75	78	81

(Cooper et al, 2010; WHO, 2010). Two limitations of such an approach are clear: First, the data are derived from a fertile population and not an infertile one, and second, the clinician cannot rely on descriptive statistics to predict outcomes. Nonetheless, the manual's tables offer the physician useful comparative information that would be otherwise unavailable in evaluating and treating infertile men.

Somewhat confusingly, the fifth edition of the manual published alongside the full percentile table a separate list of the 5th percentiles and their 95% confidence intervals (CIs) (Cooper et al, 2010; WHO, 2010). For example, the 5th percentile value for sperm density is 15 million/mL with a 95% CI range of 12 to 16 million/mL (Cooper et al, 2010; WHO, 2010). Although the authors of the companion publication to the manual very clearly describe the problems inherent in using thresholds derived from descriptive statistics of a fertile male population, the enumeration of the 5th percentile values has appeared to spur their use as new thresholds. The best use of the tables in the fifth edition of the manual would be for the urologist to present to a man alongside the patient's own parameters as a reference for an ultimately fertile population, but clinical reality dictates that both physicians and patients are interested in defining what represents infertility to consider when medical or surgical therapy is appropriately invoked. Communicating the 5th percentile value as one that likely represents infertility and the 50th percentile as typical for a man conceiving with his wife within 1 year is reasonable practice for clinical urology. As an example, for sperm density, that would be lower than 15 million/mL suggesting infertility, and 73 million/mL as typical (Cooper et al, 2010; WHO, 2010).

To complicate matters, semen analysis parameters are highly variable, and investigators typically recommend a minimum of two analyses separated by 2 to 3 weeks for assessment (Centola, 2011). Although data exist to the contrary, most investigators observe a linear decline in bulk seminal parameters with increasing days of abstinence, and variability in abstinence may be responsible for variability in semen analysis results (Levitas et al, 2005; Keel, 2006; Elzanaty, 2008). Consequently, the physician evaluating a man for his reproductive potential should ensure that the duration of abstinence before an ejaculated specimen is as constant as possible. Historically, men were instructed to wait 2 to 5 days after an ejaculation to submit a sample for semen analysis (WHO, 2010; Centola, 2011). More recent studies suggest that a single day of abstinence is optimal for assessing bulk seminal parameters (Levitas et al, 2005; Elzanaty, 2008).

A nontoxic wide-mouthed glass or plastic cup is used to collect the semen sample (WHO, 2010). In the case of religious or cultural stipulations that do not allow collection by masturbation, a special nontoxic condom may be used (WHO, 2010).

The physical and chemical characteristics of a semen sample are first assessed before microscopic examination. Ejaculated semen first forms a coagulum, and the sample is allowed to liquefy for 30 minutes before evaluation (Centola, 2011). Viscosity is assessed by aspiration into a pipette and measuring the length of the drop that forms, which should be no longer than 2 cm (WHO, 2010; Centola, 2011). The sample is then inspected visually for coloration. A normal ejaculate is white or light gray; a yellow or green hue may indicate infection, jaundice, or vitamins or medication; brown is often observed in spinal cord-injured men; and red suggests blood (WHO, 2010; Centola, 2011).

Historically, semen pH was reported, but its measurement is no longer recommended because environmental conditions may alter it, and the original intent of using pH to gauge whether obstruction exists is hampered by the vast difference in size between a hydrogen ion and sperm head (Centola, 2011). For bulk seminal parameters describing microscopic features, a specialized slide with a compartment with defined volume such as a hemocytometer or Makler counting chamber is typically used (Centola, 2011).

Semen Volume. Often unreported by laboratories infrequently performing semen analysis, semen volume is of significant clinical importance (Niederberger, 2011). Conditions causing seminal hypovolemia include anatomic factors, such as ejaculatory ductal

obstruction or hypoplasia of the prostate and seminal vesicles as may occur in severe androgen deficiency or CBAVD; functional issues, such as in retrograde ejaculation; neurologic conditions, such as in spinal cord injury, diabetes mellitus, or multiple sclerosis; and pharmacologic factors, which may occur in men prescribed α -adrenergic blocking agents such as tamsulosin (Sigman et al, 2009; Niederberger, 2011). The 5th percentile for volume according to the fifth edition of the WHO laboratory manual is 1.5 mL with a 95% CI of 1.4 to 1.7 mL, and the 2.5th percentile is 1.2 mL with a 95% CI of 1.0 to 1.3 mL (WHO, 2010). For practical purposes, the most frequently used threshold value for volume is 1.0 mL to initiate evaluation for seminal hypovolemia (Niederberger, 2011).

Aspermia, *dry ejaculate*, and *anejaculation* refer to the condition in which no fluid is discharged from the urethra during male orgasm (Sigman et al, 2009). It is caused by the same conditions associated with seminal hypovolemia (Sigman et al, 2009; Niederberger, 2011). If aspermia or seminal hypovolemia is observed, a postejaculatory urinalysis is performed to identify retrograde ejaculation, and some form of investigation such as transrectal ultrasonography (TRUS) is conducted to evaluate whether ejaculatory ductal obstruction may be present (Sigman et al, 2009; Niederberger, 2011). For postejaculatory urinalysis, the patient is instructed to void before ejaculation for a semen analysis and then to urinate after collection of the semen sample into separate containers (Sigman et al, 2009). The urine is reconstituted by centrifugation and the number of sperm in the pellet is counted (Sigman et al, 2009). A small number of sperm in the urine is of little consequence if the number of sperm in the antegrade sample is large. In general, if the number of sperm in the urine nears or exceeds that in the antegrade specimen, retrograde ejaculation is considered clinically significant (Sigman et al, 2009).

Seminal hypervolemia with an ejaculate volume exceeding 5 mL is a rare condition (Sigman et al, 2009). It is proposed to interfere with male reproduction by diluting sperm (Sigman et al, 2009). If a too-large seminal volume is of concern, the sperm may be reconstituted by processing into a smaller volume, and IUI performed (Sigman et al, 2009; Centola, 2011).

Sperm Density. Sperm density or concentration is typically recorded in millions per milliliter. The term *oligospermia* refers to low sperm density, and *cryptozoospermia* denotes sperm so few as to be difficult to reliably measure (Niederberger, 2011). The 5th percentile for sperm density according to the fifth edition of the WHO laboratory manual is 15 million/mL with a 95% CI of 12 to 16 million/mL, and the 50th percentile is 73 million/mL (Cooper et al, 2010; WHO, 2010). Previous editions of the WHO laboratory manual included a threshold for sperm density of 20 million/mL, and it was common in the past for practitioners to define oligospermia as lower than that value. With the descriptive tabulation of sperm parameters in the fifth edition of the WHO manual, oligospermia is more appropriately defined in a clinical context: A man with a single semen sample demonstrating 10 million/mL who has had no difficulty impregnating his wife may not be oligospermic, whereas one with small testes, an elevated FSH, and densities on several semen analyses ranging from 20 to 25 million/mL may be reasonably considered oligospermic. As previously written, a large CART analysis revealed 13.5 million/mL to be a lower parameter for sperm density and 48.0 million/mL to be an upper parameter (Guzick et al, 2001). In CART analysis, the ROC AUC for sperm density was 0.60, indicating relatively poor discriminating ability between fertile and subfertile subgroups (Guzick et al, 2001).

Total sperm count or number is calculated by multiplying semen volume and sperm density and is typically recorded in millions (Niederberger, 2011). The 5th percentile for total sperm number according to the fifth edition of the WHO laboratory manual is 39 million with a 95% CI of 33 to 46 million, and the 50th percentile is 255 million (Cooper et al, 2010; WHO, 2010).

Sperm Motility. Sperm motility is assessed optimally within 30 minutes of liquefaction and refers to a percentage of sperm observed with defined motion (WHO, 2010). Low motility is termed *asthenospermia* (Niederberger, 2011). The fifth edition of the WHO manual

classifies motility into three categories—progressive, nonprogressive, and immotility—replacing the four categories of older grading systems (a through d, where a and b indicated “rapid” and “slow” progressive motility) (WHO, 2010). *Progressive motility* is defined as sperm “moving actively, either linearly or in a large circle, regardless of speed,” and nonprogressive motility as “all other patterns of motility with an absence of progression” (WHO, 2010). The 5th percentile for progressive motility according to the fifth edition of the WHO laboratory manual is 32% with a 95% CI of 31% to 34%, and the 50th percentile is 55% (Cooper et al, 2010; WHO, 2010). **CART analysis revealed 32% to be a lower parameter for sperm motility and 63% to be an upper parameter (Guzick et al, 2001).** In CART analysis, the ROC AUC for sperm motility was 0.59, revealing low discriminating ability for this parameter (Guzick et al, 2001).

Sperm Morphology. Human sperm is highly pleomorphic with more bizarrely shaped sperm in any man’s ejaculate than those with configuration anticipated to successfully penetrate and fertilize an ovum (Niederberger, 2011). An overabundance of abnormal forms is termed *teratozoospermia* (Niederberger, 2011). Earlier editions of the WHO manual described fairly generous criteria as characterizing an acceptably shaped sperm, and even then, the majority of sperm were classified as misshapen in a normal semen analysis (Niederberger, 2011). **In an attempt to improve the predictive capability of sperm morphology, Kruger proposed a grading system in which several aspects of sperm were assessed, and if any one was out of range, the sperm was counted as abnormal (Kruger et al, 1987; van der Merwe et al, 2005).** This system is variably referred to as “strict” morphology, “Kruger” morphology, and “Tygerberg” morphology, and as a result of the more stringent criteria defining a normal sperm, thresholds in the range of 5% typically characterize a normal ejaculate (van der Merwe et al, 2005). The fifth edition of the WHO manual adopted strict morphology as its assessment of sperm shape (WHO, 2010). The 5th percentile for normal morphologic forms according to the fifth edition is 4% with a 95% CI of 3.0% to 4.0%, and the 50th percentile is 15% (Cooper et al, 2010; WHO, 2010). CART analysis revealed 9% to be a lower parameter for strict morphology and 12% to be an upper parameter (Guzick et al, 2001). In CART analysis, the ROC AUC for sperm motility was 0.66, as with the bulk parameters of density and motility revealing low discriminating capacity (Guzick et al, 2001).

The clinical predictive value of strict morphology is questionable. Although limited data suggest that the parameter may be associated with embryo formation, the majority of studies support that strict morphology is unassociated with sperm nuclear integrity and that it does not predict natural conception or IVF outcomes (Keegan et al, 2007; Dubey et al, 2008; Avendaño et al, 2009; Dayal et al, 2010; French et al, 2010; Sripathi et al, 2010; Morbeck et al, 2011). To complicate matters, evidence suggests that as laboratory technicians have learned to inspect each sperm more closely for eccentricities of shape, an increasing number of men are described as having lower percentages of sperm with normal morphology (Morbeck et al, 2011). The practical implication of this trend is that currently many men who seek evaluation are identified as having isolated teratozoospermia and are likely to have adequate reproductive potential.

Conditions exist in which specific biologic defects are associated with the majority of sperm. For example, should the acrosome fail to form, the preponderance of sperm will have small, round heads, a disorder referred to as *globozoospermia* (WHO, 2010). During spermiogenesis, if the basal plate does not attach to the nucleus opposite the acrosome, the heads are absorbed (WHO, 2010). This defect results in only tails observed and is termed *pinhead sperm* (WHO, 2010). Undoubtedly, these relatively uncommon specific morphologic conditions affect male reproductive potential.

Please see the Expert Consult website for further details.

Sperm Vitality. Vitality refers to the portion of sperm that are metabolically active living cells (WHO, 2010; Niederberger, 2011). *Necrozoospermia* is the condition describing a large number of nonliving sperm (Niederberger, 2011). **The assessment of whether or not sperm are living is essential if near or total asthenospermia is**

observed to discriminate whether the lack of motility is a result of cell death or of dysfunction of molecular processes involved in sperm motion (Niederberger, 2011; WHO, 2010). If the test is purely diagnostic and the sperm are not to be used in IVF, it is performed by staining with eosin Y and with or without nigrosin (WHO, 2010; Niederberger, 2011). A metabolically active sperm excludes the eosin Y dye, whereas a dead one cannot and absorbs the pigment (WHO, 2010; Niederberger, 2011). Nigrosin darkens the background and increases the contrast between it and the live sperm heads, allowing them to be identified more easily (WHO, 2010). The 5th percentile for sperm vitality according to the fifth edition of the WHO laboratory manual is 58% with a 95% CI of 55% to 63%, and the 50th percentile is 79% (Cooper et al, 2010; WHO, 2010).

A method of assessing sperm vitality in a nondestructive manner amenable to subsequent use in IVF is the hypo-osmotic swelling (HOS) test (Jeyendran et al, 1984). When incubated in hypo-osmotic medium, the tails of live sperm with unimpaired membranes swell within 5 minutes, allowing for identification of viable gametes (WHO, 2010).

Please see the Expert Consult website for further details.

Secondary Semen Assays

The haploid male gamete expresses different surface antigens than the remainder of diploid cells in the male body and consequently must be protected from the immune system by tight junctions between Sertoli cells (Walsh and Turek, 2009). Should this “blood-testis barrier” be disrupted, sperm exposed to the immune system may incite an immune response of varying severity involving secretory and humoral immunoglobulins and affecting multiple regions of the surface of the sperm cell (Walsh and Turek, 2009). **Conditions observed to be associated with antisperm antibody formation include vasectomy, testis trauma, orchitis, cryptorchidism, testis cancer, and varicocele (Walsh and Turek, 2009).**

Leukocytes may be harmful to sperm, with evidence suggesting that production of ROSs may be the destructive mechanism (Pasqualotto et al, 2000; Agarwal et al, 2006; Lackner et al, 2006; Desai et al, 2009; Domes et al, 2012; Aktan et al, 2013). Moderate levels of leukocytes in semen may be physiologic, and may even be beneficial for sperm function (Barraud-Lange et al, 2011).

Use of an assay for antisperm antibodies should be entertained if agglutination of sperm is observed or if sperm motility is decreased, especially if conditions associated with antisperm antibodies exist (Walsh and Turek, 2009; WHO, 2010; Brannigan, 2011; Niederberger, 2011). Two types of assays for antisperm antibodies are available; those that test for immunoglobulins on the surface of sperm are referred to as *direct* tests, and those that measure antibodies in fluid such as seminal plasma or serum are *indirect* assays (WHO, 2010; Brannigan, 2011). **Direct assays are preferred for clinical relevance, because antibodies in plasma or serum may not correlate to sperm surface binding (Walsh and Turek, 2009; Brannigan, 2011; Niederberger, 2011).** Owing to its large size, immunoglobulin M (IgM) is present in very low quantities if at all in semen, and consequently IgG and IgA are the primary assay targets (Walsh and Turek, 2009; Brannigan, 2011; Niederberger, 2011).

Two direct assays are available, the mixed antiglobulin reaction (MAR) test and the immunobead assay (WHO, 2010; Brannigan, 2011). The MAR test uses latex beads coated with an anti-IgG or anti-IgA “bridging” antibody incubated with sperm, whereas the direct immunobead test involves polyacrylamide beads coated with rabbit immunoglobulins against human IgG or IgA (WHO, 2010; Brannigan, 2011). **In both cases, after incubation the technician identifies the presence of antisperm antibodies by association of moving particles proximal to motile sperm, and thus some amount of sperm motion is essential for these assays; complete asthenospermia renders direct antisperm antibody assays unable to be performed (WHO, 2010; Brannigan, 2011; Niederberger, 2011).** The direct immunobead test is more laborious than the MAR assay but yields more precise information (WHO, 2010).

In an attempt to correlate sperm nuclear ultrastructure with reproductive outcomes, investigators examined sperm with an inverted light microscope outfitted with high-power Nomarski differential interference contrast optics, allowing for magnification of the field over 6000× (Bartoov et al, 2001). This technique was termed *motile sperm organelle morphology examination* (MSOME) (Bartoov et al, 2001). The theoretic advantage of MSOME is that it is a nondestructive method of assessing sperm nuclear morphology, and a sperm chosen by this method of high magnification visual inspection could be subsequently used in IVF techniques (Bartoov et al, 2001).

Early use of MSOME appeared to lead to improved pregnancy rates in IVF by screening those sperm with an overabundance of vacuoles in the sperm nucleus (Bartoov et al, 2001, 2003; Berkovitz et al, 2006). However, later studies questioned whether sperm so chosen actually led to improved IVF outcomes (Perdrix and Rives, 2013). In fact, one study argued that sperm nuclear vacuoles are a physiologic part of a normal sperm maturational process (Tanaka et al, 2012). At this point, MSOME is best considered primarily an investigational rather than a clinical tool.

Computer-Assisted Semen Analysis. Assessment of bulk seminal parameters is complex and laborious (Rothmann and Reese, 2009; WHO, 2010). The quality control mechanisms required for an accurate and reliable semen analysis performed by a capable laboratory technician are exacting and involved (Rothmann and Reese, 2009; WHO, 2010). Unfortunately, not all laboratories that offer semen analyses adhere to rigid quality assurance methods (Rothmann and Reese, 2009). It is consequently incumbent on the urologist to ensure that the semen analysis laboratory providing results uses sufficient quality standards to allow meaningful interpretation.

With the complexity associated with providing an accurate and reliable semen analysis, several manufacturers provide systems that automate the process of assessing sperm parameters such as motility, density, and morphology (Rothmann and Reese, 2009; WHO, 2010). Along with image motion analysis, these computer-assisted

semen analysis (CASA) systems also provide a variety of additional parametric assessments for moving sperm, including curvilinear velocity, rectilinear velocity, average path velocity, amplitude of lateral head displacement, linearity, wobble, straightness, beat-cross frequency, and mean angular displacement (WHO, 2010). Unfortunately, although CASA systems can rival or even exceed the precision and reproducibility of bulk semen analyses performed manually by a technician, they are still plagued by the same methodologic challenges such as optics and sample preparation, and their performance notably degrades at low sperm concentrations (Rothmann and Reese, 2009; WHO, 2010). Consequently, most high-quality laboratories combine some or much manual assistance if CASA is used (Rothmann and Reese, 2009). The highly specialized parametric assessments of motion such as curvilinear velocity are at this time primarily research rather than clinical tools (Rothmann and Reese, 2009).

The WHO laboratory manual loosely specifies 50% as a threshold for both the MAR and immunobead tests and notes that reference values are not established, leaving the interpretation of these assays to the physician considering the degree and localization of antisperm antibody binding and the clinical context (WHO, 2010). Sperm head binding is considered to be of greater clinical significance than tail binding (Niederberger, 2011).

Pyospermia Assays. Under phase contrast microscopy without staining, leukocytes and immature germ cells are indistinguishable (Brannigan, 2011). Consequently, when faced with a report indicating an abundance of cells resembling leukocytes observed only with phase contrast microscopy, the evaluating physician cannot accurately diagnose pyospermia (Brannigan, 2011). Fortunately, laboratory testing to evaluate the presence of leukocytes is not difficult. The Papanicolaou stain may be used to differentiate leukocytes from immature germ cells based on nuclear morphology (WHO, 2010). **The current consensus threshold for leukocytes according to the WHO laboratory manual is 1 million/mL (WHO, 2010).** Should pyospermia be excluded, the patient can be reassured that the presence of immature germ cells is common and not of pathologic significance (Brannigan, 2011).

Tertiary and Investigational Sperm Assays

The limitations of bulk seminal parameters spawned myriad additional means to assess sperm structure and function in hopes of better diagnosing male reproductive dysfunction, applying therapies, and predicting outcomes in techniques such as IVF. Most are promising, but few are even close to proven. Many provide insight into the biologic processes involved in reproduction, but similarly designed studies report conflicting results when these assays are applied to clinical problems. Emphasizing a lack of consensus on how they are to be used clinically, the fifth edition of the WHO manual details these assays in its “research procedures” chapter (WHO, 2010). The prudent practitioner will continue to follow the literature as it evolves and use these assays clinically should a clear consensus emerge regarding usefulness.

Sperm DNA Integrity Assays. Sperm DNA molecular and spatial organization is highly specific to cells of the male gamete. Sperm DNA is six times more compact than in somatic cells, and it is arranged with protamines to form tightly linear side-by-side sheets (Ward and Coffey, 1991). Investigators have hypothesized that fragmentation or disturbances in DNA arrangement lead to aberrations in sperm function, fertilization, implantation, and pregnancy. Conflicting data and opinions abound in testing this hypothesis, indicating that our understanding of the role of sperm DNA quaternary structure is limited, the assays available are imperfect, or both. In general, there are two types of test methods that assess DNA structural integrity (Sakkas and Alvarez, 2010). In one, DNA fragmentation is measured directly (Sakkas and Alvarez, 2010). In general, this type of assessment is preferred by andrology laboratories at present because it appears to more effectively correlate with clinical outcomes (Sakkas and Alvarez, 2010). In the other, DNA is denatured before analysis (Sakkas and Alvarez, 2010). In a comprehensive meta-analysis, higher rates of miscarriage were associated with an overall approximately double risk ratio with increasing sperm DNA fragmentation, but different assays yielded markedly different risk strengths (Robinson et al, 2012).

TUNEL Assay. The terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL) assay represents a general method in widespread use in molecular biology to assess DNA fragmentation by labeling the terminal end of nucleic acid strands with a fluorescent marker, and it was adopted in the andrology laboratory with various modifications to detect sperm head DNA fragmentation (Gavrieli et al, 1992; Mitchell et al, 2011). Figure 24-3 details one method. In panels A and B, a fluorescent stain that binds to DNA regions rich in adenine and thymine, 4',6-diamidino-2-phenylindole (DAPI), identifies sperm heads containing packed DNA. Panel A is a brightfield image that allows sperm tails to be seen, confirming that the area under scrutiny is a sperm. Panel B is a fluorescent image, allowing comparison with TUNEL-positive sperm, which are

Figure 24-3. TUNEL assay. Bright field is shown in A. Sperm heads by fluorescence are demonstrated in B. TUNEL-positive sperm are identified in C.

identified in panel C. In general, results are reported as a DNA fragmentation index (DFI), which is calculated as the ratio of TUNEL-positive sperm to all sperm and expressed as a percentage. TUNEL is considered a direct measure of sperm DNA fragmentation, and in a meta-analysis of miscarriage rates, TUNEL had the highest associated risk ratio at nearly four (Sakkas and Alvarez, 2010; Robinson et al, 2012).

Comet Assay. Like the TUNEL assay, the comet assay, also referred to as the *single-cell gel electrophoresis assay*, is widely used in molecular biology laboratories to assess DNA fragmentation and has been adopted in the andrology laboratory for sperm (Tice et al, 2000; Sakkas and Alvarez, 2010). It is a simple assay that involves migration of single sperm head DNA in an electrophoretic agarose gel, and the tail resembling a comet indicates the degree of fragmentation (Tice et al, 2000). At neutral pH, this assay is considered a direct measure of sperm DNA fragmentation (Sakkas and Alvarez, 2010). Data are conflicting regarding its use as a tool for predicting clinical outcomes (Simon et al, 2010, 2011; Ribas-Maynou et al, 2012; Robinson et al, 2012). Investigators have used the comet assay in a variety of research settings to understand the effects of various entities on sperm DNA, including varicocele, toxins, male age, and testis cancer (Meeker et al, 2004; Bertolla et al, 2006; Delbes et al, 2007; Schmid et al, 2007; Blumer et al, 2008; Meeker et al, 2008; O'Flaherty et al, 2008; Wu et al, 2009; Lacerda et al, 2011; Fariello et al, 2012b).

Denatured Sperm DNA Assays. A number of assays denature sperm DNA before structural analysis (Sakkas and Alvarez, 2010). The comet assay performed in acidic or alkaline conditions denatures DNA, and like the comet assay, the sperm chromatin dispersion (SCD) assay allows visual identification of individual sperm head DNA structure by dispersion on agarose followed by nucleic acid staining (Fernández et al, 2003; Sakkas and Alvarez, 2010). The most established assay for sperm head DNA structure is the Sperm Chromatin Structure Assay (SCSA) (SCSA Diagnostics, Brookings, SD) (Evenson and Melamed, 1983; Evenson and Jost, 2000; Larson et al, 2000; Boe-Hansen et al, 2006; Chohan et al, 2006). The SCSA does not identify individual sperm but rather a population of cells by flow cytometry after denaturation in acidic conditions followed by staining with acridine orange (Evenson and Jost, 2000; Larson et al, 2000). Graphic analysis of flow cytometric data yields several outcome parameters for SCSA, with the DFI and high DNA stainability (HDS) being the two reported in common clinical use (Evenson and Jost, 2000; Larson et al, 2000). Although a number of studies have associated human reproductive outcomes with SCSA reported values, many failed to find statistically valid correlations (Evenson and Jost, 2000; Larson et al, 2000; Payne et al, 2005; Boe-Hansen et al, 2006; Bungum et al, 2007, 2008; Lin et al, 2008). In a meta-analysis of miscarriage rates, SCSA had a risk ratio of 1.47 with a 95% CI of 1.04 to 2.09, indicating a weak likely association.

Reactive Oxygen Species. Naturally occurring chemical reactions generate highly reactive molecules with unpaired electrons termed *free radicals*. Free radicals produced from oxidative reactions are referred to as *reactive oxygen species*. ROSs are involved in multiple physiologic processes important to sperm function, but investigators theorize that if present in excess, seminal ROSs may cause reproductive dysfunction (Agarwal et al, 2006, 2008c; Desai et al, 2009). TAC may be quantified in seminal fluid, and one popular method of quantifying how ROSs may affect sperm function is calculation of a ROS-TAC score (Rice-Evans and Miller, 1994; Sharma et al, 1999). Researchers have assessed ROS activity in aging, prostatitis, varicocele, lubricants, radiation, smoking, toxins, and obesity (Pasqualotto et al, 2000; Smith et al, 2005; Cocuzza et al, 2008a, 2008b; Farombi et al, 2008; Pasqualotto et al, 2008a; Agarwal et al, 2009; Hsu et al, 2009; Palmer et al, 2012; Taha et al, 2012; Agarwal et al, 2013).

Sperm Ultrastructural Assessment. MSOME involving sperm head morphologic inspection with high-power Nomarski differential interference contrast optics that magnify the field over 6000× is discussed in the section on sperm morphology in this chapter. Although electron microscopy is widely used in scientific research on the male gamete, it also has a place in the clinical assessment

of the infertile male (Chemes and Rawe, 2003). Sperm motility is dependent on the ultrastructural arrangement of microtubules in the tail with a peripheral array of nine pairs and a central two microtubules connected by dynein arms (Chemes and Rawe, 2003). This “9 + 2” architecture is shared with cilia, and genetic disorders affecting it can manifest as respiratory pathology associated with male reproductive dysfunction, referred to as the *immotile cilia syndrome*, *primary ciliary dyskinesia* (PCD), or *Kartagener syndrome* (Eliasson et al, 1977; Guichard et al, 2001; Chemes and Rawe, 2003). Kartagener syndrome results in sperm that are nearly totally or completely immotile but metabolically active (Peeraer et al, 2004). Semen samples with less than 10% motility and vitality demonstrated by testing may be investigated with electron microscopy to assess tail ultrastructural defects (Zini and Sigman, 2009). Electron microscopy is not available in all andrology laboratories.

Genomic Assessment

As odd as it may be to imagine that genes passed from parent to male offspring may be responsible for a condition that, if left untreated, would prevent those genes from being passed to future generations, evidence suggests that genetics plays a significant role in male reproductive dysfunction (Oates and Lamb, 2009). Known genetic conditions associated with the male sex are detailed in later sections of this chapter. In this section, clinically available assays are described.

Karyotype

Staining chromosomes with dyes binding to various moieties of the chemical structure of DNA resulting in banding patterns represents the classic means of cytogenetic analysis of chromosomes (Swansbury, 2003). Fluorescence in situ hybridization (FISH) uses fluorescent probes hybridizing to determined sequences on chromosomes, allowing for identification of specific regions or entire chromosomes depending on the specificity of the probe (Swansbury, 2003). One advantage of FISH is that it offers the ability to investigate the cytogenetics of both somatic and germ cells, which may differ beyond the expected halving of chromosomes (Martin, 2008). Other techniques, such as the spectral karyotype (SKY), use combinatorial methods to visualize all chromosomes in multiple colors (Swansbury, 2003). The American Urological Association Best Practice Statement on the Optimal Evaluation of the Infertile Male recommends that genetic testing including karyotype be performed in all males with azoospermia caused by spermatogenic dysfunction and in those with severe oligospermia defined as less than 5 million sperm/mL (Jarow et al, 2010). However, as numerical and structural chromosomal anomalies vary by geographic region, and obtaining a karyotype may represent a significant expense to the patient, the treating physician may judge whether this assay is indicated in his or her patient population.

Y Chromosome Microdeletion Testing

The Y chromosome is one of the smallest in humans at approximately 60 mega base pairs (Mb) (Tilford et al, 2001; Navarro-Costa, 2012). It is the determinant of the male gender and is the only chromosome passed directly from father to son (Navarro-Costa, 2012). It consists of a male-specific region with no homologous chromosomal mate and a pseudoautosomal region (Graves et al, 1998; Tilford et al, 2001; Navarro-Costa, 2012). In an elegant series of cytogenetic analyses for the time, Tiepolo and Zuffardi determined in 1976 that a region in the long arm of the Y chromosome was critical to the formation of sperm in man, which became known as AZF (azoospermia factor) (Tiepolo and Zuffardi, 1976; Chandley et al, 1989).

The portion of the Y chromosome that does not recombine represents approximately 95% of its sequence (Tilford et al, 2001). About one third of this nonrecombinant region consists of palindromic inner sequences present at least twice in forward and reverse

Functional sperm have an appendage at the head originating from the Golgi apparatus termed the *acrosome*, which primarily contains hydrolytic enzymes necessary for entering the ovum (Cross and Meizel, 1989). After binding to the zona pellucida of the ovum, the acrosome releases its contents, and the sperm penetrates the zona pellucida. Owing to its importance in normal fertilization,

investigators have devised ways of assessing acrosomal function, the first being fluorescent labeling of acrosomal contents (Cross and Meizel, 1989). Subsequent use of flow cytometry allowed real-time analysis of acrosomal function (Zoppino et al, 2012). Tests of acrosomal function are not in common clinical use and primarily serve as research tools.

Interaction with cervical mucus is a prerequisite for successful transit of sperm through the female reproductive tract. The postcoital test, also known as the *Sims-Huhner test*, assesses sperm interaction with mucus in two parts: first, it appraises mucus characteristics favorable to sperm penetration; and second, it gauges the number and motility of observed sperm ([Griffith and Grimes, 1990](#)). Although the postcoital test has been used by clinicians for a very long time, it suffers from a lack of standardization and reproducibility ([Griffith and Grimes, 1990](#)). Furthermore, researchers have demonstrated that medical history and semen analysis could accurately replace the postcoital test result in approximately half of couples ([van der Steeg et al, 2004](#)).

In an attempt to standardize and improve reproducibility of assessment of sperm interaction with cervical mucus, investigators

devised model systems in which sperm and mucus could be observed ex vivo ([Niederberger et al, 1993](#)). The Penetrak assay standardized the female component by replacing human with bovine cervical mucus and measuring the penetration of sperm in the latter, and the Tru-Trax assay provides two wells, allowing sperm penetration to be compared in either human and bovine cervical mucus or with either donor and patient sperm ([Niederberger et al, 1993](#)). Although bulk seminal parameters measure typical populations of sperm, evidence suggests that these standardized sperm-mucus interaction assays assessed motility of the unusual sperm that would ultimately fertilize the ovum ([Niederberger et al, 1993](#)). These assays are not presently in common clinical use.

Final structural barriers to the sperm on its journey through the female reproductive include the zona pellucida, the species-specific barrier to sperm, and the oolemma, and investigators have designed assays for both (Zini and Sigman, 2009). In the sperm penetration assay (SPA), hamster zona pellucida are removed, and human sperm are incubated with the denuded hamster ova, simulating IVF (Yanagimachi et al, 1976; Margalioth et al, 1986). Results of the SPA are reported as either percentage of ova penetrated or average number of sperm penetrating ova (Zini and Sigman, 2009). Before ICSI, clinicians used SPA results to counsel patients about the likelihood of IVF success; after the introduction of ICSI, clinicians used SPA results to decide whether ICSI was preferable to incubational IVF (Zini and Sigman, 2009). With widespread use of ICSI as a primary modality for IVF, the SPA is currently rarely used. Researchers also developed a modified SPA to predict ICSI outcomes in which sperm are microinjected directly into hamster ova and nuclear decondensation is assessed (Gvakharia et al, 2000). Because the majority of couples undergoing ICSI would do so independently of prognostication based on this assay, the SPA modified for ICSI is not in common clinical use.

Andrology laboratory investigators designed assays to investigate the initial union of sperm and ovum—the binding to the zona pellucida (Yanagimachi et al, 1979; Burkman et al, 1988; Liu and Baker, 1988; Coddington et al, 1991; Liu and Baker, 1992). These tests compare subject with control sperm binding to the zona pellucida (Burkman et al, 1988; Liu and Baker, 1988; Coddington et al, 1991; Liu and Baker, 1992). Either the zona can be halved, with each half subjected to subject or control sperm, or sperm may be labeled and differentiated visually with fluorescent microscopy (Burkman et al, 1988; Liu and Baker, 1988; Liu and Baker, 1992). The test using halves of ova is referred to as the *hemizona assay* (HZA) (Burkman et al, 1988; Coddington et al, 1991). Whereas ova may be stored in salt for use when needed, the fact that the zona pellucida is the species-specific barrier to sperm requires that human ova be used to assess zona binding (Yanagimachi et al, 1979; Burkman et al, 1988; Liu and Baker, 1988; Coddington et al, 1991; Liu and Baker, 1992). Owing to the paucity of human sources and readily available ova, the HZA is rarely used.

reading frames referred to as *amplicons* (Tilford et al, 2001). This sequence structure is believed to substitute in part in place of sexual recombination in repair of the Y chromosome but may also engender a particular fragility in increasing the likelihood of the loss of segments, or microdeletions (Oates and Lamb, 2009). Based on the work of Tiepolo and Zuffardi, investigators observed microdeletions of three regions on the Y chromosome to be commonly associated with azoospermia or oligospermia, which were termed AZFa, AZFb, and AZFc (Oates and Lamb, 2009). Once thought to be separate and distinct regions, AZFb and AZFc overlap, whereas AZFa is distant and isolated (Jobling and Tyler-Smith, 2003). The *DAZ* genes, believed to be integrally associated with spermatogenesis, are housed within the AZFc region (Saxena et al, 2000). Investigators have also referred to the proximal portion of AZFc as *AZFd*, but the usefulness of isolating this subregion remains unclear (Müslümanoğlu et al, 2005).

Some microdeletions of AZFc appear to be associated with spermatogenic impairment but not failure (Mulhall et al, 1997; Oates et al, 2002). Likewise, the clinical relevance of analysis of AZFc subregions such as gr/gr is unclear, because sperm may be present in the ejaculate and in the testis (Lardone et al, 2007; Wu et al, 2007; Giachini et al, 2008; Stouffs et al, 2008; Visser et al, 2009). However, evidence strongly suggests that AZFa and AZFb microdeletions cause significant pathology of the testis resulting in diminishing low likelihood of sperm retrieval by surgery (Hopps et al, 2003). **It is reasonable practice to recommend Y chromosomal microdeletion assessment to azoospermic men before surgical sperm extraction to counsel them on the likelihood of retrieval (Jarow et al, 2010).** However, it is also reasonable to omit testing based on the relative rarity of AZFa and AZFb microdeletions in clinical practice.

Genomic Sequence Assessment

A variety of technologies such as DNA microarrays allow multiple single nucleotide polymorphisms (SNPs) and mutations associated with known diseases to be screened for and reported (Schena et al, 1995; Hunter et al, 2008; Lizarin et al, 2013). These reports can be used to identify whether parents are carriers for a large number of genetic diseases and the probability of affected offspring. Whole genome sequencing as a clinical tool is also under current development (Moorthie et al, 2013). Although these technologies may ultimately be used to diagnose underlying causes of male reproductive dysfunction, use as general screening tools in evaluating male infertility is not yet warranted.

Cystic Fibrosis Transmembrane Conductance Regulator Mutation Assessment

The relationship between alterations in the cystic fibrosis transmembrane conductance regulator (CFTR) and maldevelopment of the vas is discussed in the section on developmental disorders in this chapter. This section describes what testing is available.

The protein encoded by CFTR forms a channel for chloride ions and possibly bicarbonate and may serve to regulate transport of other ions (Hampton and Stanton, 2010). More than 1600 CFTR mutations have been identified, and they may be mild or severe, defined by whether the full cystic fibrosis disease phenotype results from the mutation (Ratbi et al, 2007; Oates and Lamb, 2009; Hampton and Stanton, 2010; Bombieri et al, 2011; Yu et al, 2012). **The most common severe mutation is $\Delta F508$, which results from deletion of three base pairs that consequently remove the amino acid phenylalanine typically at position 508 of the encoded protein (Hampton and Stanton, 2010).** A high incidence of patients harbor more than one mutation; approximately 46% have two (Yu et al, 2012). A severe mutation such as $\Delta F508$ on each allele will result in a child with cystic fibrosis, making screening imperative for both the prospective father and mother for those suspected of harboring genetic alterations in CFTR.

Currently available CFTR screening panels typically include 25 to 40 of the most common mutations. Because a subset of known mutations is screened for, a negative result still carries a defined risk. Testing is commercially available for all known mutations but is expectedly more expensive. CFTR mutation prevalence varies by ethnicity and geography (Hamosh et al, 1998; Boyd et al, 2004; Foresta et al, 2005; Schulz et al, 2006; Ratbi et al, 2007; Havasi et al, 2010; Li et al, 2010; Bombieri et al, 2011). Consequently, the clinician should take into account location and ethnicity in interpreting results. Typically, CFTR screening panel reports are stratified by ethnicity.

KEY POINTS: LABORATORY EVALUATION OF MALE INFERTILITY

- Endocrine assessment of male reproductive status includes total testosterone, the portion of testosterone not bound to SHBG, estradiol, and the pituitary gonadotropins LH and FSH.
- The semen analysis represents a probabilistic assessment of male reproductive potential. Aside from azoospermia, no specific threshold applied to any parameter absolutely discerns infertility from fertility.
- The differential diagnosis for men with semen volumes less than 1.0 mL includes ejaculatory ductal obstruction, retrograde ejaculation, and vasal and accessory sex gland maldevelopment such as that occurring with CBAVD.
- Sperm vitality staining differentiates complete asthenospermia from necrospermia. Common laboratory staining methods differentiate pyospermia from immature germ cells.
- A preponderance of sperm with round heads, a condition referred to as *globozoospermia*, indicates deficient acrosome formation. The treatment is IVF with ICSI.
- Disruption in the blood-testis barrier formed by tight junctions between Sertoli cells results in antisperm antibodies, which have varying clinical significance depending on the degree of binding to sperm heads.
- Genetic screening of the CFTR in men with CBAVD and their partners identifies the presence of severe mutations such as $\Delta F508$ that may result in clinically overt cystic fibrosis in offspring.

IMAGING IN THE EVALUATION OF MALE INFERTILITY

Radiographic or ultrasonographic imaging is infrequently needed in the diagnosis of male reproductive dysfunction and should be **ordered cautiously**. Likely benign conditions such as testicular microlithiasis may be detected, resulting in patient distress and often unnecessary additional testing (Dagash and MacKinnon, 2007). The following descriptions of imaging in the evaluation of male reproductive dysfunction should not be interpreted as indicated in typical screening.

Scrotal Ultrasonography

Evaluation of the infertile male includes a detailed manual examination of the scrotum and its contents. As with the scrotal physical examination for any urologic evaluation, abnormalities may be detected that warrant scrotal ultrasonography for further investigation. In Figure 24-4, color duplex Doppler ultrasonography demonstrates a varicocele. Panel A reveals the varicocele to be adjacent to the testis, and the colored areas in panel B demonstrate the direction of flow. The diameter of the largest vein can be measured and reported.

Ultrasonography of the spermatic cord may be indicated if the evaluating physician is uncertain whether a varicocele is present on palpation (Nagler and Grotas, 2009). However, the varicoceles so identified are often so small as to be of questionable clinical

Figure 24-4. Color duplex Doppler ultrasonography of scrotum demonstrating varicocele. Dilated veins adjacent to the testis are exhibited in A, and directional flow in the vessels is revealed in B.

significance. Varicoceles become palpable at approximately 2.7 to 3.6 mm in diameter, and surgical treatment of varicoceles smaller than 3.5 mm that are not palpable on physical examination but observed on ultrasound does not result in improved seminal outcomes (Eskew et al, 1993; Hoekstra and Witt, 1995; Jarow et al, 1996; Schiff et al, 2006). Consequently, the most rational approach based on whether identification of a varicocele is likely to affect treatment outcomes is not to rely on ultrasound as a necessary diagnostic tool.

Direction of flow may be assessed by color Doppler ultrasound, and investigators have reported that reversal of flow is a positive prognostic sign that surgical treatment of varicocele may result in improved seminal parameters (Hussein, 2006; Schiff et al, 2006). At this time, insufficient numbers of men with nonpalpable varicoceles that are identified with reversal of flow are reported in studies investigating surgical treatment to conclude that color Doppler ultrasound is indicated as a screening modality for infertile men.

In conjunction with TRUS, investigators have observed sensitivity of 75% and specificity of 72% for diagnosing azoospermia caused by spermatogenic dysfunction and sensitivity of 29.8% and specificity of 87% for diagnosing azoospermia caused by obstruction (Abdulwahed et al, 2013). However, given the high accuracy in differentiating azoospermia caused by spermatogenic dysfunction versus obstruction yielded by measuring testis longitudinal axis and assaying serum FSH, it seems more prudent and cost-effective not to use ultrasonography in an attempt to diagnose the cause of azoospermia in men with adequate seminal volumes.

Vasography

Contrast vasography in the direction of the abdomen allows determination of patency of the vas deferens from the scrotum to the

Figure 24-5. Transrectal ultrasonography revealing an intraprostatic cyst. A is transverse, and B is longitudinal. (Courtesy Marcelo Vieira.)

ejaculatory ducts (Ammar et al, 2012). It is currently rarely performed because image modalities such as TRUS and magnetic resonance imaging (MRI) have superseded it; it is invasive and may result in scar tissue formation in the vasal lumen and obstruction; and injection of saline into the vasal lumen during intended vasal reconstructive procedures with the manual feedback of whether fluid flows easily or backflow occurs offers similar information. Fluid, contrast or otherwise, should never be injected into the vasal lumen in the direction of the epididymis because it will rupture the delicate epididymal tubules. Should backflow be identified during intraoperative saline vasography, a monofilament suture such as 4-0 polypropylene may be inserted into the vasal lumen, advanced until resistance is encountered, and then withdrawn and the distance measured to determine the location of the obstruction.

Venography

Please see the Expert Consult website for details.

Transrectal Imaging

The diagnosis of ejaculatory ductal obstruction is considered when azoospermia in conjunction with low seminal volume is encountered (Niederberger, 2011). The earliest and still currently the most prevalent method of investigating whether ejaculatory ductal obstruction in present is TRUS (Jarow, 1996; Niederberger, 2011). TRUS imaging evidence of ejaculatory duct obstruction includes an anteroposterior seminal vesicle diameter of greater than 1.5 cm with or without a midline prostatic cyst (Jarow, 1996; Niederberger, 2011; Ammar et al, 2012). Figure 24-5 demonstrates an intraprostatic cyst, with panel A exhibiting the transverse view and panel B the longitudinal view. Unfortunately, although TRUS is convenient and common, its specificity is low compared with other modalities for identifying whether or not obstruction is

Venography is rarely performed for the diagnosis of varicocele. For the same reasons that scrotal ultrasound is infrequently necessary (i.e., clinically significant varicoceles are palpable and require no further imaging, and the treatment of varicoceles that are identifiable only by imaging and are not palpable does not improve

seminal outcomes), venography is usually not useful in assessing the import of a varicocele. If a clinically significant varicocele is to be treated by embolization, then venography is used to plan the radiographic interventional approach.

Figure 24-6. Large pituitary macroadenoma revealed by cranial magnetic resonance imaging.

present (Purohit et al, 2004). These other assessments include radiographic imaging after injection of contrast directly into the seminal vesicles, or vesiculography; aspiration of the seminal vesicles to determine whether sperm is present; and injection of diluted indigo carmine or methylene blue dye into the seminal vesicles and observation by cystoscopy of whether the colored dye flows from the ductal orifices at the verumontanum, a technique referred to as *chromotubation* (Purohit et al, 2004). In a small series, vesiculography and chromotubation were more accurate than TRUS by a margin of 25% (Purohit et al, 2004). However, these techniques are more invasive and expensive, and an incremental improvement in diagnostic accuracy compared with TRUS if conclusively demonstrated in larger studies may not justify the additional risk and cost.

Please see the Expert Consult website for further details.

Abdominal Imaging

Please see the Expert Consult website for details.

Cranial Imaging

Cranial MRI allows assessment of whether hyperprolactinemia is associated with an anatomic pituitary lesion (Niederberger, 2011). MRI may distinguish between microadenomas and macroadenomas and may assist in judging whether medical or surgical therapy is indicated (Johnsen et al, 1991). Figure 24-6 demonstrates a cranial MRI revealing a large pituitary macroadenoma.

KEY POINT: IMAGING

- Imaging can reveal sequelae of genetic conditions such as congenital absence of the vas deferens and renal aplasia, and it can differentiate reasons for seminal hypovolemia such as ejaculatory ductal obstruction, but it is infrequently necessary to establish diagnoses such as varicocele or spermatogenic dysfunction.

ASSISTED REPRODUCTION

Please see the Expert Consult website for details.

DIAGNOSES AND THERAPIES

The understanding of the pathophysiology of male reproductive dysfunction has expanded in past years but remains manifestly incomplete. The difficulties inherent in the probabilistic nature of reproduction and its assessment pose challenges to the physician evaluating and consequently treating male infertility, but sufficient information is known for the treating physician to make reasoned assumptions about whether a pathologic explanation involving the man exists, its likely basis, and plausible therapy. This section reviews discrete diagnoses and possible medical therapies.

Genetic Syndromes

With the completion of sequencing of the human genome in 2004, knowledge of how the genes involved in human reproduction conspire to create fully formed and viable sperm will follow (International Human Genome Sequencing Consortium, 2004). As discussed in the section of this chapter describing genomic sequence assessment, broad panels are available that identify carrier risk of known genetic diseases, and whole genomic sequencing is under development. However, current use of the former and use of the latter, should it become immediately available, as general screening tools for male reproductive dysfunction are hampered by the lack of an understanding of how the majority of the genetic mechanisms involved in spermatogenesis function in concert to produce viable sperm. A certain number of genetic associations are known to be involved in male infertility, and these are detailed in subsequent sections. In this section, general genetic causes of male fertility involving chromosomal number, structure, and epigenetic mechanisms are discussed.

Chromosomal Numerical Disorders

The presence of a supernumerary X chromosome yielding 47,XXY, or Klinefelter syndrome, is the most commonly identified genetic cause of male infertility (Oates and Lamb, 2009; Sigman, 2012; Groth et al, 2013). A 47,XXY genotype is observed in 1 in 500 to 1000 live births, and in over 95% of affected adults results in azoospermia, small testes, and elevated gonadotropin levels (Maiburg et al, 2012; Groth et al, 2013). Approximately 75% of children have learning disabilities, and 63% to 85% of men have low testosterone levels (Groth et al, 2013). Body morphology features such as increased height are observed in only 30% of Klinefelter males, and consequently the condition cannot be excluded by physical examination and physical inspection alone (Groth et al, 2013). Increased incidence of other disorders related to the testis such as mediastinal germ cell tumors is documented in men with Klinefelter syndrome, suggesting broader testicular effects (Sokol, 2012).

A nonmosaic 47,XXY karyotype is observed in 80% to 90% of men with Klinefelter syndrome (Maiburg et al, 2012). The remainder are mosaic 46,XY/47,XXY or have additional or structurally abnormal X chromosomes (Maiburg et al, 2012). In the man, approximately 8% have sperm in the ejaculate, and the remainder are azoospermic (Oates, 2012). Within the testis, approximately half of men with Klinefelter syndrome have sufficient mature sperm amenable to surgical sperm retrieval for use with IVF and ICSI (Oates, 2012). Early age at diagnosis appears to offer a more favorable prognosis (Mehta and Paduch, 2012).

Until recently, fertility management of men with Klinefelter syndrome was limited to diagnosing the condition with karyotype analysis, assessing whether sperm was present in the ejaculate, and attempting to extract sperm from the testis if it was not. Many of these men are identified shortly after puberty with low testosterone levels and prescribed exogenous testosterone alone, suppressing native spermatogenesis if present. Citing the progressive decline

TESTIS HISTOPATHOLOGY

Please see the Expert Consult website for details.

MRI with an endorectal coil can be used to evaluate anatomic features consistent with ejaculatory ductal obstruction (Engin et al, 2000). It suffers from the same challenges as ultrasound, which is that ejaculatory ductal obstruction may not correlate with the observed anatomy. In one study comparing TRUS and MRI, MRI identified 23% of anatomic aberrations that were not discernible on TRUS (Engin et al, 2000). However, the clinical significance of these additional identified lesions is not established, and TRUS found anomalies not observed by MRI (Engin et al, 2000). Engin and coworkers concluded that TRUS is a good screening modality and that MRI should be reserved for situations in which TRUS results are ambiguous (Engin et al, 2000).

As with any hydraulic system, anatomic features may not correlate to resistance, which is ultimately a functional assessment of

flow and pressure. Investigators have described use of manometry to establish baseline functional characteristics of the ejaculatory ducts (Eisenberg et al, 2008). In one method, dye was injected into the seminal vesicles until it could be visualized with a cystoscope flowing from the ductal orifices at the verumontanum, and the pressure at that point was measured (Eisenberg et al, 2008). In another method, a constant infusion flow was applied to the seminal vesicles, and the pressure was measured (Eisenberg et al, 2008). Investigators have also injected technetium-99m-containing solution into the seminal vesicles and assessed emptying over time by scintigraphy (Orhan et al, 2008). These promising procedures should not yet be considered standard evaluation until further studies have established validity.

Abdominal imaging in the evaluation of the infertile male is primarily used to study whether renal sequelae of congenital vasal maldevelopment is present. As previously described, unilateral absence of the vas deferens may be associated with loss of wolffian

ductal development on that side and renal agenesis, and a solitary kidney was observed in one of nine men with CBAVD ([Schlegel et al, 1996](#); [Niederberger, 2011](#)). Renal ultrasound is typically sufficient to identify whether both kidneys are present.

Historically, men found to have azoospermia were subject to testis biopsy to diagnose whether the condition was caused by obstruction or spermatogenic dysfunction. However, as previously described, the majority of azoospermic men can be successfully diagnosed with a single laboratory assay and one measurement on physical examination (Schoor et al, 2001). The combination of the FSH assay result and testis size as measured by caliper or orchidometer accurately predicts whether azoospermia is the result of obstruction or spermatogenic dysfunction: 96% of men with obstructive azoospermia had FSH assay values of 7.6 IU/L or less and testis long axis greater than 4.6 cm, and 89% of men with azoospermia caused by spermatogenic dysfunction had FSH values greater than 7.6 IU/L and testis long axis 4.6 cm or less (Schoor et al, 2001). Coupled with the observation that a biopsy in one location of the testis does not predict histopathology and full spermatogenesis in other areas, the fact that the prognostic information afforded by biopsy could be supplanted with FSH and testis longitudinal axis called into question the value of testis biopsy in the evaluation of male reproductive dysfunction in general (Turek et al, 1997; Schoor et al, 2001; Ramasamy and Schlegel, 2007). Consequently, testis biopsy is not indicated in the initial diagnostic evaluation of the infertile man.

Men with infertility and azoospermia in particular appear to be at increased risk for certain diseases such as cancer (Walsh et al, 2010; Eisenberg et al, 2013). This observation is not unexpected, because azoospermia is likely to result from dysregulation of molecular systems that may be associated with oncogenesis. Hence, testis biopsy simultaneously with other procedures such as testis sperm extraction may yield pathologic information that can explain procedural outcomes as well as provide information about other related future diseases.

Testis biopsy should be considered as an incomplete sampling of testicular histology and germ cell development. In one series, one third of men who underwent testis biopsy that demonstrated no sperm were found to have sperm at a site distant from the biopsy location (Turek et al, 1997). In another series assessing outcomes of microsurgical testis sperm extraction in which the testis was globally and systematically visually explored for tubules likely to contain sperm, approximately two of five men with one or two prior biopsies demonstrating no germ cells were found to have mature sperm (Ramasamy and Schlegel, 2007). Even with three or four prior biopsies with only Sertoli cells seen, mature sperm was extracted in one of nine men (Ramasamy and Schlegel, 2007). These observations confirm that spermatogenesis may be highly focal in men with azoospermia, and a biopsy may not describe the entirety of the histology of a testis.

Should biopsy be performed in conjunction with testis sperm extraction to sample testis histology, spermatogenesis is typically characterized histologically by light microscopy as to whether germ cells are present at all, and if so, the volume of active spermatogenesis and the degree of development of the farthest advanced cell. In the most extreme case, germ cells are lacking entirely and only Sertoli cells are visible in the germinal epithelium. This condition is often referred to as *Sertoli cell-only syndrome* and is demonstrated by low-power light microscopy in Figure 24-7. For comparison, Figure 24-8 exhibits normal spermatogenesis on light microscopy. The low-power view in panel A reveals a robust and full seminiferous epithelium with a variety of germ cells in various stages of spermatogenesis. In the high-power view demonstrated in panel B, the arrow indicates the typical triangular shape of a mature sperm head. As sperm develop in a three-dimensional epithelial surface, it is unusual to find an entire mature sperm with its full tail in one single microscopic plane. Consequently, visualization of a mature sperm head is typically sufficient to confirm completion of the stages of spermatogenesis.

Figure 24-9 reveals general depopulation of the seminiferous epithelium. A variety of germ cells in differing stages of spermatogenesis are observed, but the seminiferous epithelium appears diminished in luminal caliber. This condition is referred to as *hypospermatogenesis*. In Figure 24-10, varying stages of spermatogenesis are observed but without completely formed sperm. This condition

Figure 24-7. Low-power light microscopy demonstrating Sertoli cell-only syndrome.

Figure 24-8. Light microscopy demonstrating normal spermatogenesis. A is low power, and B is high power. The arrow in B indicates a mature sperm head.

is referred to as *maturation arrest*. Spermatogenesis may be arrested before meiotic division, which is termed *early maturation arrest*, or during or after meiotic division, which is referred to as *late maturation arrest* (Alukal et al, 2009). In Figure 24-10, small nuclei consistent with postmeiotic germ cells are observed but not maturing or mature sperm; this is therefore considered late maturation arrest.

KEY POINT: TESTIS HISTOPATHOLOGY

- In general, testis biopsy is unnecessary to identify whether azoospermia is the result of spermatogenic dysfunction or obstruction; 96% of men with obstructive azoospermia have FSH assay values of 7.6 IU/L or less and testis long axis greater than 4.6 cm, and 89% of men with azoospermia caused by spermatogenic dysfunction have FSH values greater than 7.6 IU/L and testis long axis of 4.6 cm or less.

Figure 24-9. Low-power light microscopy demonstrating hypospermatogenesis.

Figure 24-10. Low-power light microscopy demonstrating maturation arrest.

Reproductive medicine is unique in that it includes not one but two patients for a healthy outcome to occur. For natural conception, pregnancy, and delivery, a functional female reproductive system must be present, and coitus must be occurring at regular intervals. Several methods may be used by specialists in female fertility to control variables related to conception and the female reproductive tract. The urologist treating the infertile male works closely in integrated fashion with the gynecologist or reproductive endocrinologist caring for his partner. Even when the female reproductive system is fully functional and normal on evaluation, these methods may be used to overcome male factors impeding fertilization.

As previously described, chronologic age is a significant determinant of female reproductive potential, especially in the consideration of the use of more invasive reproductive techniques (te Velde and Pearson, 2002; Balasch and Gratacós, 2012). Female fecundity begins to decline after age 35, and this decline accelerates after age 37 (Van Voorhis, 2011; Balasch and Gratacós, 2012). The urologist must take into account maternal age and other female factors when planning therapy for the man. Because spermatogenesis is a lengthy process, treatment directed toward improving it and waiting to determine the effect may be appropriate with a female partner at age 30 years, but more aggressive therapy for the couple including more invasive techniques for the woman may be better suited should she be 38 years of age.

In assessing success rates for any therapy directed toward reproduction, outcomes must be carefully identified. If the embryo is cultured outside of the woman's body, a fertilization rate may be calculated. Pregnancy rate is different and greater than delivery rate, with the latter of greater interest to the couple.

Intrauterine Insemination

In general, external augmentation of reproduction takes two forms. In one form, semen is delivered by instrumentation into the female reproductive tract. The most common type of this form is IUI, during which a small catheter is placed through the cervical os to deliver sperm directly into the uterus, thus bypassing the cervical barrier (Van Voorhis, 2011). Often, sperm are processed in the laboratory to enrich the motile fraction before IUI. IUI decreases in effectiveness when the number of motile sperm in the ejaculate is low, in general considered to be in the range of less than 10 million, or if the motile sperm in the processed sample total fewer than 1 million (Van Voorhis, 2011).

Table 24-3 lists outcome data for various interventions for the female partner based on 2008 national data from SART (Van Voorhis, 2011). IUI alone results in an average per-cycle delivery rate of 5%; adding the oral medicine clomiphene citrate increases it to 8%, and adding the injectable medication human menopausal gonadotropin (hMG) increases the delivery rate to 15% to 18% (Van Voorhis, 2011).

The essential value of IUI is that it controls variables related to the initial voyage of sperm in the reproductive tract. Should the penile urethra, vaginal vault, and cervix be misaligned or hostile, IUI begins the journey of sperm at a point within the uterus. Sperm must then transit through the fallopian tubes to ultimately join the ovum, but a considerable barrier to reproduction is bypassed.

TABLE 24-3 Per-Cycle Success Rates of Various Forms of Intervention for the Female Partner and the Associated Multiple Birth Rate Based on 2008 National Data from the Society for Assisted Reproductive Technologies (SART)

TECHNIQUE	DELIVERY RATE OR CYCLE	MULTIPLE BIRTH RATE OR PREGNANCY
Timed intercourse	2%-3%	1%
IUI alone	5%	1%
Clomid alone	5%	10%
Clomid and IUI	8%	10%
hMG alone	12%-15%	15%
hMG and IUI	15%-18%	15%
In vitro fertilization	30%-32%	31%

hMG, human menopausal gonadotropin; IUI, intrauterine insemination. From Van Voorhis BJ. What to know about the infertile female. In: Niederberger CS, editor. An introduction to male reproductive medicine. New York: Cambridge University Press; 2011. p. 134–51.

In Vitro Fertilization

A variety of methods currently exist to manipulate gametes and embryos outside of a woman's body and to return the results into the female reproductive tract. These techniques are collectively known as *assisted reproductive technologies* (ART). With the culmination of a great body of scientific work leading to the first live birth reported in 1978 after incubation of sperm and ovum outside of a mother who had both fallopian tubes removed and replacement of the embryo into her uterus, an entirely new way of treating both female and male infertility was born (Stephens and Edwards, 1978). Later, investigators developed methods of inserting a single sperm into an ovum, dramatically lowering the number of male gametes needed for IVF (Palermo et al, 1992).

ICSI revolutionized IVF, allowing consideration of sperm that had not transited the epididymis for use in ART. Shortly after its introduction, investigators began to compare ICSI outcomes for sperm derived from the testis and epididymis, finding that fertilization and pregnancy rates were similar (Ubaldi et al, 1996; Watkins et al, 1997). Subsequent studies confirmed these initial observations and demonstrated that ICSI was equally effective with sperm from either testicular or epididymal origin (Nicopoullos et al, 2004; Kalsi et al, 2010). ICSI also made possible usage of cryopreserved testicular sperm for ART, which has the advantage of permitting the man and woman to undergo testicular sperm extraction and ova retrieval on separate days and also the benefit to the female reproductive specialist and couple of knowing whether biologic sperm could be procured before hormonal stimulation of the woman (Gil-Salom et al, 1996; Friedler et al, 1997; Prins et al, 1999). Investigators have observed similar outcomes when using ICSI with cryopreserved testicular sperm and sperm extracted from the testis on the day of ova retrieval (Nicopoullos et al, 2004; Kalsi et al, 2010).

in spermatogenesis over time, investigators have argued for aggressive management including surgical extraction of sperm at early to mid puberty before initiation of therapy with exogenous testosterone (Mehta and Paduch, 2012). This approach is primarily investigational at this time.

Structural Chromosomal Anomalies

As discussed in the section detailing Y chromosome microdeletion testing, investigators observed three regions on the Y chromosome, designated AZFa, AZFb, and AZFc, to be associated with azoospermia or oligospermia (Oates and Lamb, 2009). Microdeletions of AZFc currently have unclear clinical significance, whereas AZFa and AZFb microdeletions are nearly always associated with absence of retrievable sperm from the testis (Mulhall et al, 1997; Oates et al, 2002; Hopps et al, 2003; Lardone et al, 2007; Wu et al, 2007; Giachini et al, 2008; Stouffs et al, 2008; Visser et al, 2009). AZFa microdeletions have particular clinical significance, as spatially the AZFa region appears to be localized distinctly from AZFb and AZFc, with the latter two overlapping (Oates and Lamb, 2009).

Other structural anomalies of the Y chromosome may be identified by karyotypic analysis (Oates and Lamb, 2009). Two terminal breaks in both chromosome arms and subsequent fusion may lead to a ring Y chromosome, or r(Y), with variable phenotype depending on the amount of chromosomal material lost (Arnedo et al, 2005). Karyotypic anomalies in somatic chromosomes may also be associated with infertility (Mau-Holzmann, 2005).

Epigenetic Anomalies

Not only must the DNA sequence be intact for successful function of the male gamete, the DNA must be tightly coiled and packaged (O'Flynn O'Brien et al, 2010). As discussed in the section describing denatured sperm DNA assays, investigators have constructed various methods of interrogating sperm DNA structure with unclear prognostic outcomes at present. Other components of sperm DNA packaging may yield future diagnostic tools; for example, animal studies revealed that premature translation of protamine 1 resulted in postmeiotic maturational arrest in mouse spermatogenesis, and protamine 2 deficiency led to sperm DNA damage and embryo demise (Lee et al, 1995; Cho et al, 2003). In humans, evidence links protamine 2 precursors and the protamine 1–protamine 2 ratio to sperm DNA quality and IVF outcomes (Aoki et al, 2006; Torregrosa et al, 2006; de Mateo et al, 2009). Histones also offer a future target for clinical assessment. They are highly specifically localized along human sperm DNA, and researchers have observed histone variants to relate to fertility in bulls (Hammoud et al, 2009; de Oliveira et al, 2013).

DNA methylation allows coordination of gene expression in somatic cell development (Boissonnas et al, 2013). Once thought to be of little consequence in sperm, this epigenetic modification is now considered to play key roles in spermatogenesis and embryogenesis (Molaro et al, 2011; Carrell, 2012; Boissonnas et al, 2013). The pattern of gene promoter methylation is substantially different in somatic and sperm cell DNA and may have future clinical applicability in the assessment of male reproductive potential (Molaro et al, 2011).

Testicular Causes

The testis essentially consists of two compartments, the seminiferous tubules that house the developing male gametes and the interstitial spaces between the tubules, inhabited by Leydig cells. Both are required for sperm production, which then must conclude with transit of the male gamete outward. Testicular causes of male reproductive dysfunction may consequently be considered to derive from pathology in the production of sperm in the seminiferous epithelium or in the synthesis of testosterone by Leydig cells, or obstruction in the microductal system transporting sperm toward the ejaculatory ducts.

Spermatogenic Dysfunction

As discussed in the section describing testis histopathology, dysfunction in the seminiferous epithelium may be globally described as hypospermatogenesis, which indicates a decrease in sperm production; maturation arrest, which represents halting of the sequence of steps of the male gamete at some point through premeiotic, meiotic, and postmeiotic development; and Sertoli cell–only syndrome, which denotes a complete depopulation of spermatogonial cells. The molecular mechanisms leading to completion of spermatogenesis are still under investigation, and in the future it is likely that genomic, proteomic, and metabolomic markers will become available for clinical use to diagnose specific causes of spermatogenic dysfunction (Kovac et al, 2013). At present, the primary means of assessing deficiencies in spermatogenesis is histopathologic inspection. As previously described, should azoospermia be present, in 89% of cases spermatogenic dysfunction is identified as the cause with an FSH value greater than 7.6 IU/L and the testis long axis 4.6 cm or less (Schoor et al, 2001).

Another form of spermatogenic pathology arises in the testis and impedes sperm in the ejaculate. In the seminiferous epithelium, Sertoli cell tight junctions protect haploid germ cells from circulating immunologic cells, forming a blood–testis barrier (Brannigan, 2011). Pathologic conditions that disrupt this blood–testis barrier may expose the immunologically protected spermatids and spermatozoa to antibody formation, which may cause sperm agglutination, impeded sperm motility, and reduced fertilizing potential (Brannigan, 2011). These conditions include obstruction in the male reproductive tract such as that occurring after vasectomy; inflammation associated with orchitis, prostatitis, or sexually transmitted disease; exposure to heat with varicocele, cryptorchidism, or external sources such as hot tubs; trauma and testis torsion; and genetic associations including thymic maldevelopment and the HLA-B28 haplotype (Walsh and Turek, 2009). Assays for antisperm antibodies are detailed in the section describing the laboratory evaluation of semen.

For treatment of antisperm antibodies, simple measures include use of condoms and washing sperm. Neither has good evidence to substantiate its use (Walsh and Turek, 2009). Washing may remove unbound antibodies, but those that matter remain bound to sperm (Walsh and Turek, 2009). More direct treatments include immunosuppression with corticosteroids and ART. Two controlled trials of corticosteroids offer conflicting results, with one demonstrating improved fertility and the other not (Haas and Manganiello, 1987; Hendry et al, 1990). Whether because of a lack of compelling evidence or because of more direct results, IVF and ICSI have become common treatment for antisperm antibodies.

Steroidogenic Dysfunction

The terms hypergonadotropic hypogonadism, primary hypogonadism, and primary hypoandrogenism refer to impaired testosterone synthesis caused by Leydig cell dysfunction (Sokol, 2009). This entity is typically identified by elevated LH levels and decreased circulating testosterone (Sokol, 2009). However, Leydig cell dysfunction may exist concurrently with pituitary insufficiency, and these men will have decreased testosterone concentrations and variable LH levels that do not reflect the typical increase associated with primary Leydig cell insufficiency (Sokol, 2009). Increasing age is a condition associated with decreasing androgen and blunted pituitary response (Feldman et al, 2002; Sokol, 2009).

An absolute requirement for spermatogenesis is intratesticular steroidogenesis, which appears to be especially important for the postmeiotic maturation of sperm (Caroppo, 2011). Men with Klinefelter syndrome often have lower levels of circulating testosterone, but impaired Leydig cell function may not be the only mechanism responsible for a phenotype that resembles those of hypoandrogenic males (Sokol, 2009; Oates, 2012). Investigators have reported evidence of Leydig cell dysfunction in humans associated with mutations in the LH receptor gene and in FSH receptor–deficient mice, and as the genes responsible for steroidogenesis become

clinically available for assessment in humans, it is anticipated that more cases of Leydig cell dysfunction with genetic causes will be identified (Latronico et al, 1996; Baker et al, 2003). Other potential clinical causes of Leydig cell dysfunction include orchitis, cytotoxic chemotherapy, and exposure to environmental toxicants (Skakkebaek et al, 2001; Sokol, 2009).

There is currently no accepted therapy for hypoandrogenism caused by Leydig cell insufficiency (Sokol, 2009). Exogenous testosterone is not indicated, because insufficient testicular testosterone concentrations are achieved for spermatogenesis, and pituitary LH release is suppressed (Niederberger, 2011). **Should azoospermia be associated with low testosterone concentrations and significantly elevated LH levels, if the patient desires paternity, the treatment is surgical sperm extraction.**

Microductal Obstruction

Either by congenital or acquired means, the epididymis or scrotal vas deferens may be obstructed. If obstruction is bilateral, azoospermia typically results. As discussed in the section describing the endocrine evaluation, the physician may use the FSH level combined with the testis longitudinal axis as measured by calipers to predict whether azoospermia is associated with obstruction; 96% of men with obstructive azoospermia had FSH concentration of 7.6 IU/L or less and testis long axis greater than 4.6 cm (Schoor et al, 2001). **Figure 24-11** illustrates an algorithm for the evaluation of azoospermia. Microductal obstruction may also be unilateral: in that case, bulk seminal parameters may be reduced or not depending on the function of the contralateral testis. Should unilateral obstruction be present with adequate spermatogenesis present in the ipsilateral testis and the existence of spermatogenic pathology in the contralateral testis, impaired bulk seminal parameters may result and microductal reconstruction may be indicated.

As discussed in the section describing evaluation of the surgical history of an infertile male, herniorrhaphy especially with mesh may result in obstruction of the vas deferens in the inguinal canal (Shin et al, 2005; Maciel et al, 2007; Hallén et al, 2011, 2012; Tekatli et al, 2012). If both vasa are occluded, azoospermia likely results.

Pituitary Dysfunction

The pituitary hormones LH and FSH regulate spermatogenesis: LH directs Leydig cell steroidogenesis; and FSH controls spermatogenesis via the Sertoli cells (Caroppo, 2011). If by intrinsic dysfunction or external pathology LH, FSH, or both are suppressed, spermatogenesis suffers.

Hypogonadotropic Hypogonadism

Hypogonadotropic hypogonadism refers to the condition of decreased pituitary hormonal secretion. Kallmann described anosmia associated with decreased pituitary function, and the syndrome bears his name (Kallmann and Schoenfeld, 1944). The incidence of the syndrome is approximately one in 10,000 males, and the mode of inheritance is most frequently autosomal recessive, but autosomal-dominant and X-linked recessive patterns are also observed (Bhagavath et al, 2006; Sokol, 2009). Investigators have identified associations with Kallmann syndrome and the *KAL1* gene encoding anosmin-1 responsible for neurotropic growth factors during embryogenesis, the *GNRHR* gene encoding gonadotropin-releasing hormone (GnRH) receptor, the pituitary-specific transcription factor *PIT1*, the *PIT1*-related transcription factor *PROP1*, the G protein-coupled Kisspeptin receptor *GPR54*, the homeobox genes *HESX1*, *LEX3*, and *LEX4*, and others (Dattani et al, 1998; Wu et al, 1998; de Roux et al, 2003; Kim et al, 2003; Sobrier et al, 2004; Bhagavath et al, 2006; Newbern et al, 2013). Researchers noted approximately 10% of men with Kallmann syndrome to harbor mutations in either the *GNRHR* or *KAL1* gene (Bhagavath et al, 2006).

Treatment includes replacement of LH with human chorionic gonadotropin (hCG) and replacement of FSH with recombinant FSH (rFSH) or hMG, which exhibits both LH and FSH-like activity (Sokol, 2009). Treatment with hCG alone may initiate spermatogenesis; if hMG or rFSH is prescribed, after spermatogenesis returns, these agents may be withdrawn after several months of therapy (Sokol, 2009). Men who are identified as having Kallmann syndrome later in life when reproductive interests occur have often been prescribed exogenous androgen since adolescence. These men may require gonadotropin therapy for 1 to 2 years before sperm becomes evident in the ejaculate. Typical doses for intramuscular or subcutaneous hCG are 1500 to 5000 international units two to three times weekly to a maximum of 10,000 international units per week and are titrated to serum testosterone results (Sokol, 2009; Hussein et al, 2013). The dose of hMG is 75 international units two to three times weekly, typically administered subcutaneously (Sokol, 2009).

Rarely, men may have isolated decreased secretion of either LH or FSH (Giltay et al, 2004; Sokol, 2009). Isolated LH deficiency was termed the “fertile eunuch syndrome” and characterizes men who have features of hypoandrogenism owing to low levels of LH but who produce sperm as a result of adequate FSH (Sokol, 2009). Conversely, men with isolated FSH deficiency have suppressed spermatogenesis but adequate androgenization (Giltay et al, 2004).

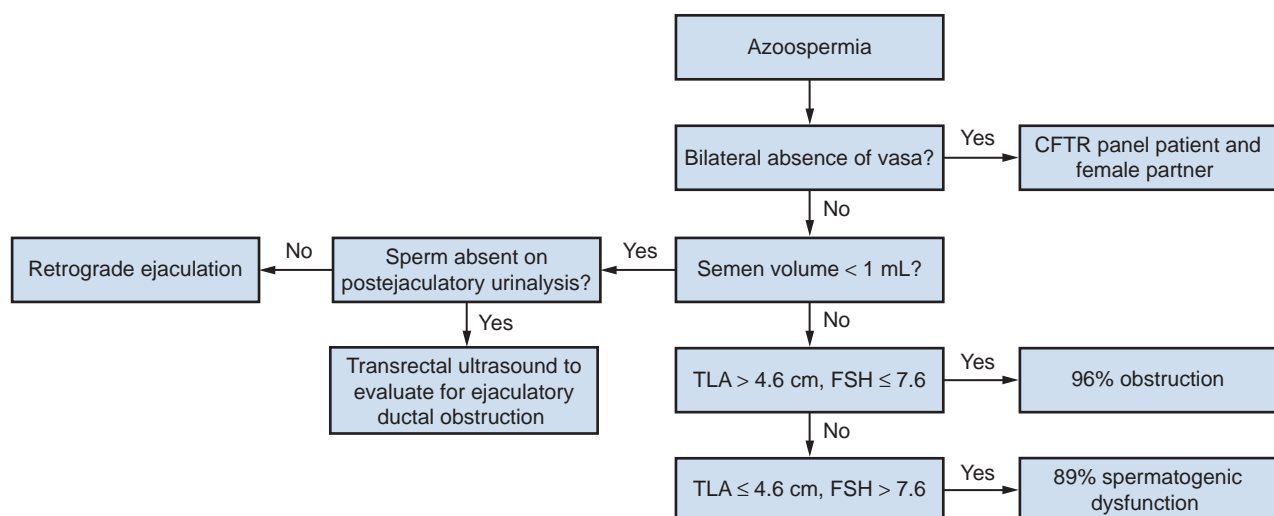

Figure 24-11. Algorithm for evaluation of azoospermia. CFTR, cystic fibrosis transmembrane conductance regulator; FSH, follicle-stimulating hormone; TLA, testis longitudinal axis measured by caliper orchidometer.

Treatment of these uncommon conditions includes replacement with the appropriate gonadotropin (Giltay et al, 2004; Sokol, 2009). Men may also infrequently have isolated hypothalamic GnRH deficiency (Nachtigall et al, 1997). Treatment includes GnRH administration by a subcutaneous portable mini-infusion pump every 2 hours, and, as with treatment for Kallmann syndrome, long-term courses of at least 6 months' duration may be required (Nachtigall et al, 1997).

Kallmann and the associated syndromes of hypogonadotropic hypogonadism are the most severe forms of conditions resulting in diminished pituitary hormonal secretion. **Incomplete forms with hypoandrogenism associated with serum LH concentrations above those observed with Kallmann syndrome but lower than expected for the diminished testosterone are common** (Bhagavath et al, 2006). For these men, pituitary stimulation with anti-estrogenic agents such as clomiphene or tamoxifen or with aromatase inhibitors such as anastrozole or letrozole may restore testosterone levels and possibly improve spermatogenesis (Raman and Schlegel, 2002; Siddiq and Sigman, 2002; Hussein et al, 2005; Ioannidou-Kadis et al, 2006; Whitten et al, 2006; Sussman et al, 2008; Katz et al, 2012; Moskovic et al, 2012; Hussein et al, 2013; Roth et al, 2013). The initial dose of clomiphene citrate is typically 25 mg every day or 50 mg every other day and is increased by titrating to serum testosterone to a maximum of 100 mg daily (Hussein et al, 2005; Sussman et al, 2008; Hussein et al, 2013). In some studies, the titration target is restoration of normal androgen levels; in others, it is elevated at 600 to 800 ng/dL (Hussein et al, 2005; Sussman et al, 2008; Hussein et al, 2013). The typical dose of anastrozole is 1 mg daily (Raman and Schlegel, 2002).

Prader-Willi syndrome is characterized by failure to thrive in infancy associated with a poor suck reflex followed by loss of satiety in early childhood, which may lead to marked obesity if poorly controlled (Cassidy and Driscoll, 2009). Its incidence is approximately 1 in 15,000 to 30,000 (Cassidy and Driscoll, 2009). Features associated with the syndrome include hypogonadism, small testes, dysmorphic facies, growth hormone deficiency with short stature and small hands and feet, pain insensitivity, and cognitive disorders such as obsessive-compulsive traits (Bervini and Herzog, 2013). Researchers have suspected that the association of growth hormone deficiency and hypogonadism with the syndrome derive from hypothalamic dysfunction, but the precise pathophysiology is still uncertain (Bervini and Herzog, 2013). Prader-Willi syndrome is typically caused by the loss of expression of genes located on human chromosome 15q11-q13 by means of failed imprinting, which is the epigenetic phenomenon that allows genes on only one chromosome to be active (Bervini and Herzog, 2013). In the healthy state, the genes located on the maternal chromosome 15q11-q13 are silenced, and those on the paternal chromosome are active; in Prader-Willi syndrome, the maternal genes are silenced and the paternal ones inactive (Bervini and Herzog, 2013).

Pituitary Tumors and Diseases

Space-occupying lesions in the sella turcica such as secretory and nonsecretory tumors and craniopharyngiomas may compress the anterior pituitary and result in varying degrees of LH and FSH suppression (Sokol, 2009). The most common kind of pituitary tumor resulting in male reproductive dysfunction secretes prolactin and is commonly associated with other symptoms such as erectile dysfunction (Sokol, 2009). These tumors are rare; as described in the section discussing the endocrine evaluation, in one series of 1035 men undergoing an infertility evaluation, only 4, or 0.4%, had hyperprolactinemia (Sigman and Jarow, 1997). This finding questions the value of including prolactin as a routine assay in screening infertile men, especially those who are otherwise asymptomatic (Sigman and Jarow, 1997; Sokol, 2009; Niederberger, 2011). In general, mild elevations of prolactin in the range of 20 to 50 µg/L do not warrant further evaluation; if prolactin is significantly elevated, cranial MRI is indicated (Niederberger, 2011). The dopamine agonists bromocriptine and cabergoline may be prescribed for

prolactin-secreting adenomas for which surgery is not indicated, with cabergoline exhibiting fewer side effects (Klibanski, 2010).

Other Pituitary Lesions

Diseases infiltrating the pituitary may also suppress its secretion of hormones, including granulomata of infection, sarcoidosis, and histiocytosis (Sokol, 2009). Deposition of iron by hemochromatosis or repeated blood transfusions may also invoke hypogonadotropic hypogonadism (Sokol, 2009). Systemic diseases such as morbid obesity, chronic malnutrition, and type 2 diabetes may also be associated with hypogonadotropic hypogonadism (Dhindsa et al, 2004; Sokol, 2009). Treatment of these disorders is aimed at ameliorating the underlying condition.

Extrapituitary Endocrine Modulators

As described in the section discussing the role of investigating endocrine modulators when taking the history of an infertile man, exogenous androgenic agents, especially testosterone, suppress pituitary gonadotropins (Grimes et al, 2012). Also discussed in that section are cannabis, antipsychotics, opioids, and environmental toxicants, which inhibit pituitary function via estrogenic and dopaminergic pathways (Carlsen et al, 1992; Stimmel and Gutierrez, 2006; Gorzalka et al, 2010; Subirán et al, 2011). Treatment is directed toward removing the offending agent when possible. CAH, especially in milder forms that manifest clinically in adolescence or adult life, may be associated with hypogonadotropic hypogonadism (Reisch et al, 2011). A high incidence of testicular adrenal rest tumors adds to the reproductive dysfunction present in these men (Claahsen-van der Grinten et al, 2008; Reisch et al, 2011). Fertility may be restored with corticosteroid therapy (Claahsen-van der Grinten et al, 2007). However, side effects such as weight gain and skin changes from the lengthy application of therapy required to address the long duration of spermatogenesis may prove problematic (Claahsen-van der Grinten et al, 2007).

Extratesticular Endocrine Dysfunction

Because estradiol inhibits gonadotropin release, conditions that increase its concentration may lead to hypogonadotropic hypogonadism. These include the pharmacologic agents described in the section discussing medications that alter the ratio of estrogen to androgen through a variety of means (Bowman et al, 2012). When possible, use of another agent may improve fertility. As described in the section discussing the general physical examination of the infertile male, elevated estradiol is associated with obesity by the mass of adipose cells containing aromatase (Hammoud et al, 2006; Aggerholm et al, 2008; Chavarro et al, 2010; Hammoud et al, 2010b; Hofny et al, 2010). Multiple factors are suspected to associate obesity with male infertility, and hypogonadotropic hypogonadism may or may not be involved (Hammoud et al, 2006; Aggerholm et al, 2008; Pauli et al, 2008; Hofny et al, 2010; Paasch et al, 2010; Teerds et al, 2011). The question remains regarding whether diet, exercise, and weight reduction improve male reproductive potential. Limited animal studies in an obese rodent model suggest that diet and exercise improve sperm parameters, but human studies are sparse and inconclusive (Nguyen et al, 2007; Braga et al, 2012; Palmer et al, 2012; Luconi et al, 2013). In the absence of conclusive data demonstrating a causative effect between weight loss and improved male fertility, it still seems prudent to recommend it in obese men because the ancillary health benefits are certain.

Researchers have investigated the use of aromatase inhibitors such as anastrozole, letrozole, and testolactone for elevated estradiol, demonstrating that for the typical male patient, testosterone levels increase and estradiol levels decline (Raman and Schlegel, 2002; Gregoriou et al, 2012; Schlegel, 2012). Limited data support that sperm parameters may concurrently improve (Raman and Schlegel, 2002; Gregoriou et al, 2012; Schlegel, 2012). As described in the section discussing the endocrine evaluation of male infertility, researchers have proposed that a testosterone-to-estradiol ratio

in nanograms per deciliter (ng/dL) to picograms per milliliter (pg/mL) of less than 10:1 indicates aromatase overactivity that would benefit from inhibitory therapy (Raman and Schlegel, 2002; Gregoriou et al, 2012; Schlegel, 2012). Prescribers should be cautious in the long-term use of aromatase inhibitors, because bone density in the male may be estradiol dependent, and long-term studies of this class of drug in men are lacking (Khosla et al, 2001; Kim et al, 2013).

Mutations in the androgen receptor (AR) gene located on the long arm of the X chromosome at banding region Xq11-12 lead to a spectrum of disorders from complete testicular feminization to male infertility (Dowsing et al, 1999; Davis-Dao et al, 2007; Sokol, 2009). Male reproductive dysfunction appears to be related to a longer cytosine-adenine-guanine (CAG) repeat length in exon one of the AR gene (Dowsing et al, 1999; Davis-Dao et al, 2007; Sokol, 2009). Male infertility associated with AR insensitivity is characterized by increased testosterone, estradiol, and LH to variable degrees with typical FSH levels; significantly elevated testosterone in the presence of impaired male fertility should consequently raise the suspicion of AR resistance (Sokol, 2009). High-dose testosterone therapy may result in improved spermatogenesis, but data on this form of treatment are limited (Tordjman et al, 2014). Pregnancy may be achieved by ICSI with ejaculated sperm or that derived by surgical extraction from the testis (Massin et al, 2012; Tordjman et al, 2014).

Because dihydrotestosterone regulates the anatomic development of external male genitalia, mutations in the gene encoding isozyme 2 of 5 α -reductase located on the short arm of chromosome 2 at banding region 2p23 result in a spectrum ranging from a female to a male phenotype (Johnson et al, 1986; Thigpen et al, 1993; Sokol, 2009). Phenotypic females with 5 α -reductase 2 mutations may harbor testes with intact spermatogenesis (Johnson et al, 1986; Thigpen et al, 1993). No medical treatment is currently available for this disorder. Pregnancies have been successfully attained with ICSI from sperm from men with 5 α -reductase-2 deficiency (Matsubara et al, 2010; Kang et al, 2011).

Developmental Disorders

Anatomic development that results in aberrant genital formation may manifest in later life as male infertility. Main areas of maldevelopment include the testes, the external genitalia, and the reproductive microductal system.

Intersex or Disorders of Sexual Development

Previously, intersex was divided into categories such as male pseudohermaphroditism, female pseudohermaphroditism, true hermaphroditism, and mixed or complete gonadal dysgenesis, with true hermaphrodites having components of both ovaries and testes (Oates and Lamb, 2009; Ono and Harley, 2013). Disorders of sex development (DSDs) are increasingly being understood as the consequence of specific aberrant genes, and the current nomenclature used to describe intersex now includes the karyotype, a clinically descriptive term, and the molecular basis of the disorder if it is known (Ono and Harley, 2013). An example of an intersex description using this nomenclature might be "46,XY DSD complete gonadal dysgenesis with SF1 mutation" (Ono and Harley, 2013). Genes identified to be involved in DSD are too numerous to be listed here, and the reader is referred to Ono and Harley for a current review (Ono and Harley, 2013). In general, the genes involved in DSDs that manifest as male infertility do so by developmental anatomic abnormalities, abnormal or absent spermatogenesis, general endocrinopathy, or encoding for defective endocrine receptors and target complexes (Oates and Lamb, 2009; Ono and Harley, 2013).

Hypospadias and Epispadias

Aberrant anatomic location of the urethra in hypospadias or epispadias may result in deposition of semen too distal in the vaginal

vault (Niederberger, 2011). These men may have adequate bulk seminal parameters, and if screening semen analysis is performed before physical examination of the man, the diagnosis may be missed. Hypospadias appears to have both genetic and environmental causes, with genetic polymorphisms playing a predominant role rather than isolated gene defects (Macedo et al, 2012). The pathophysiology of epispadias is different from that of hypospadias, and it is typically considered on the spectrum of bladder-exstrophy-epispadias complex (BEEC) disorders (Rasouly and Lu, 2013).

Cryptorchidism

The basis of cryptorchidism and the relationship of the disorder to male reproductive function is detailed in the section of this chapter describing childhood diseases in the reproductive history of the infertile male. The most significant feature related to the prognosis of cryptorchidism is whether the condition is unilateral or bilateral (Lee et al, 2001; Miller et al, 2001; Lee, 2005).

Microductal Aplasia

The vas deferens may fail to develop on one side or both. The distinction is significant, as the pathophysiologic basis of each is different.

Congenital Unilateral Absence of the Vas Deferens. As described in the section detailing the physical examination of the infertile male, unilateral absence of the vas deferens implies that wolffian, or mesonephric, ductal development on the ipsilateral side was aberrant. As these ducts become in embryogenesis the epididymis, vas deferens, and ejaculatory duct, the proximal and distal portions may be malformed or absent as well (Lewis and Kaplan, 2009). The most important consideration if unilateral absence of the vas is observed is that because renal development is coupled with wolffian ductal development, a solitary absent vas deferens may signal renal agenesis (Niederberger, 2011).

Congenital Bilateral Absence of the Vas Deferens. Oates and colleagues reported in the early 1990s that males with CBAVD had a high frequency of genetic sequence abnormalities associated with cystic fibrosis (Anguiano et al, 1992). Coupled with the observation that in nearly all men with cystic fibrosis the vasa are absent bilaterally, these findings suggested that CBAVD is frequently a phenotype for a spectrum of disorders involving mutations in the gene responsible for cystic fibrosis (Anguiano et al, 1992). As described in the section discussing genomic sequence assessment in the laboratory evaluation of the infertile male, that gene encodes a predominantly chloride ion channel termed the *cystic fibrosis transmembrane conductance regulator*, and currently more than 1600 mutations in the gene have been identified, which vary in the severity of the phenotype from CBAVD to cystic fibrosis (Ratbi et al, 2007; Oates and Lamb, 2009; Hampton and Stanton, 2010; Bombieri et al, 2011; Yu et al, 2012).

It is currently believed that two genetic causes of CBAVD exist: one that results from mutations in CFTR, and another that results from alterations in as-yet-unidentified other genes involved in mesonephric ductal development (Oates and Lamb, 2009). CFTR mutations represent a spectrum of disease severity; should both alleles harbor severe mutations, cystic fibrosis results, and if one or both alleles contain the milder forms, CBAVD may occur (Ratbi et al, 2007; Oates and Lamb, 2009; Hampton and Stanton, 2010; Bombieri et al, 2011; Yu et al, 2012). As described in the section detailing genomic sequence assessment, the most common mutation is $\Delta F508$, which is severe (Hampton and Stanton, 2010). The carrier frequency for cystic fibrosis gene mutations is high—approximately 1 in 20 in persons of Northern European descent—and it is consequently important to investigate the CFTR status of the female partner of a man identified to have CBAVD in addition to his genetic evaluation (Oates and Lamb, 2009). Symptoms such as chronic sinus or respiratory infections may be overlooked if mild, and the urologist diagnosing CBAVD might be the first to uncover an indolent form of cystic fibrosis (Oates and Lamb, 2009).

Spermatogenesis in men with CBAVD is typically normal, and ICSI with surgically extracted sperm is typically effective (Kamal et al, 2010). Genetic counseling taking into account the CFTR genetic assessment of the affected man and his female partner allows for the couple to understand the likelihood of cystic fibrosis in offspring and the implications of carrier status, and it may be performed by the urologist or a clinical geneticist.

Varicocele

The diagnosis of varicocele was discussed in the section detailing the physical examination of the infertile man: why imaging such as ultrasound is most rationally not recommended for the screening evaluation of a varicocele is discussed in the section describing imaging.

That most men with varicocele have sperm present on semen analysis has proved to be one of the most confounding aspects of its diagnosis and treatment. As discussed in the section describing the semen analysis, the results of this assay are assessed in a probabilistic context with substantial variability, making analytical statements concerning its effect on male reproductive potential difficult. Taking into account confounding factors involving the female partner that are often opaque and difficult to control in analyses, determining the effect of a varicocele on pregnancy, miscarriage, and birth becomes intractable. However, substantial evidence links varicocele to spermatogenic dysfunction and impaired male reproductive potential.

Because the left internal spermatic vein drains into the left renal vein approximately 8 to 10 cm superior to the entry of the right internal spermatic vein draining into the vena cava, the hydrostatic column of blood on the left predisposes that side to incompetence in its venous valves more so than on the right (Shafik and Bedeir, 1980; Gat et al, 2005; Masson and Brannigan, 2014). **As a result, varicose veins in the pampiniform plexus are more common on the left than on the right (Gat et al, 2005; Masson and Brannigan, 2014).** The incidence of bilateral varicoceles depends on the techniques involved in detection, with over 80% observed to be bilateral on contact thermography, Doppler sonography, and venography in one series (Gat et al, 2004). Whether these bilateral varicoceles so identified are clinically significant remains an open question. **One clinical consequence of the infrequency of solitary right varicoceles is that should one be identified, renal pathology such as tumor should be considered, especially if the right-sided varicocele is of abrupt onset (Masson and Brannigan, 2014).**

Varicoceles likely arise as most varicose veins do by intravenous valvular incompetence (Wishahii, 1991; Gat et al, 2005). Genetics may predispose to a valvular defect, as investigators have noted an increased incidence of varicoceles in first-degree relatives of men with a known varicocele (Raman et al, 2005).

Substantial evidence correlates the presence of palpable varicoceles to male reproductive dysfunction. Bulk seminal parameters are poorer in men with varicocele than in the fertile population (WHO, 1992; Al-Ali et al, 2010). Testis size, which reflects the mass of spermatogenesis, is smaller in men with varicocele, and investigators have documented progressive atrophy associated with the condition (Lipshultz and Corriere, 1977; Sakamoto et al, 2008; Patel and Sigman, 2010).

Most studies investigating how varicocele exerts deleterious effects on male reproductive function consider the primary event to be an increase in intratesticular temperature secondary to interruption in the counter-current heat exchange provided in the pampiniform plexus with opposing flow vectors in a central arterial system and surrounding veins (Zorgniotti and MacLeod, 1973; Goldstein and Eid, 1989; Masson and Brannigan, 2014). The proposed mechanisms by which male fertility is impaired by this effect mainly include DNA fragmentation and apoptosis, oxidative stress, predisposition to aneuploidy, and intracellular metabolic and ionic changes (Benoff et al, 2004; Smith et al, 2005; Baccetti et al, 2006; Bertolla et al, 2006; Enciso et al, 2006; Lima et al, 2006; Zucchi et al, 2006; Shiraishi and Naito, 2007; Agarwal et al, 2008c; Blumer et al, 2008; Pasqualotto et al, 2008a; Ghabili

et al, 2009; Wu et al, 2009; Abd-Elmoaty et al, 2010; El-Domyati et al, 2010).

Ejaculatory Dysfunction

Disorders of ejaculation may be anatomic, functional, or neuropathic in origin, resulting in absence of emission, resistance, or misdirection. The three main categories of ejaculatory dysfunction encountered in a clinical setting include ejaculatory ductal obstruction, retrograde ejaculation, and anejaculation.

Ejaculatory Ductal Obstruction

The ejaculatory ducts are primarily intraprostatic structures that originate at the terminus of the seminal vesicles and serve as their extensions but without their musculature, functioning within the prostate as simple conduits (Nguyen et al, 1996). The ampulla of the vas enters the prostate medially and at an acute angle with the terminating limb of the seminal vesicle (Nguyen et al, 1996). The intraprostatic conduit ends angled at the verumontanum, which contains two layers of longitudinal muscular bundles extending into the urethra (Nguyen et al, 1996).

Obstruction of the ejaculatory ducts is infrequent and is the cause of azoospermia in less than 5% of men without sperm in the ejaculate (Wosnitzer and Goldstein, 2014). It may occur at any point along the transit of the ducts within the prostate and result from infection, inflammation, prior surgery, or compression by congenital cysts (Wosnitzer and Goldstein, 2014). As detailed in the section discussing the semen analysis, an evaluation for ejaculatory ductal obstruction is indicated when the seminal volume is less than 1.0 mL. As noted in the section describing imaging to evaluate for ejaculatory ductal obstruction, techniques to investigate it include TRUS, MRI, chromotubation, and hydraulic pressure measurements. If clinically significant ejaculatory ductal obstruction is suspected and if the position of the obstruction is amenable to surgery, treatment is surgical resection.

Retrograde Ejaculation

Ejaculation is a multiphasic event that includes coordinated neural activity and muscular contraction and relaxation (Jefferys et al, 2012; Phillips et al, 2014). Afferent genital stimulation and cognitive ideation initiate the process, which induces emission through sympathetic stimulation of the bladder neck, vasal ampullae, seminal vesicles, and prostate (Jefferys et al, 2012; Phillips et al, 2014). **Essential to antegrade ejaculation, the bladder neck must first close while temporal neural sequencing first causes closure of the external sphincter to create a high pressure compartment that is emptied with its subsequent opening (Shafik, 1995).**

Failure of sufficient resistance at the bladder neck during generation of the high-pressure system within the prostatic urethra may redirect emission into the bladder, causing retrograde ejaculation. Pathologic causes include congenital abnormalities of or surgery to the bladder neck, spinal cord or neural injury during trauma or retroperitoneal lymph node dissection, diabetes mellitus, or idiopathic causes (Jefferys et al, 2012). **Like ejaculatory ductal obstruction, retrograde ejaculation is infrequent and is established as the diagnosis in less than 2% of infertile men (Jefferys et al, 2012).**

As detailed in the section discussing the semen analysis, an evaluation for ejaculatory ductal obstruction is indicated when the seminal volume is less than 1.0 mL and includes a postejaculatory urinalysis, which is considered significant if the number of sperm in the urine nears or exceeds that in the antegrade specimen (Sigman et al, 2009). **Primary treatment modalities include retrieval of retrograde ejaculated sperm and increasing resistance at the bladder neck with sympathomimetic agents.** In both cases, the sperm so obtained is processed for use in IUI or IVF. If retrieval is to be attempted, the urine is typically first alkalinized with oral bicarbonate or diluted by oral fluid intake, and then the voided urine or a catheterized specimen is obtained after masturbation and orgasm (Jefferys et al, 2012). Investigators have also described

ejaculation on a full bladder with successful results (Crich and Jequier, 1978; Templeton and Mortimer, 1982). Clinicians may also use sympathomimetic agents such as synephrine, pseudoephedrine, ephedrine, or phenylpropanolamine, with approximately one in four patients achieving antegrade ejaculation (Jefferys et al, 2012). Researchers have described other therapy such as anticholinergic agents, acupuncture, and surgery, but these should be considered investigational (Jefferys et al, 2012).

Anejaculation

Anejaculation refers to lack of seminal emission and projectile ejaculation, and it must be distinguished from anorgasmia, in which the absence of an ejaculation has a cerebral cause (Brackett et al, 2009). Conditions that result in anejaculation are primarily neurologic and include retroperitoneal lymph node dissection, pelvic surgery, multiple sclerosis, transverse myelitis, congenital neural tube defects, diabetes mellitus, and spinal cord injury (Brackett et al, 2009; Phillips et al, 2014).

For patients with sufficient peripheral neural function, neurostimulation with penile vibratory devices or application of current with a rectal electrode, or electroejaculation, may result in sufficient sperm for IUI or IVF (Brackett et al, 2009; Phillips et al, 2014). For men with spinal cord injuries at a level of T6 or above, stimulation may cause autonomic dysreflexia, an uninhibited sympathetic reflex accompanied by headache, diaphoresis, hypertension, bradycardia, and diaphoresis, which may be life-threatening. Autonomic dysreflexia can be addressed before stimulation by treatment with nifedipine and during the procedure with monitoring of cardiac activity and blood pressure (Brackett et al, 2009; Phillips et al, 2014).

The sperm achieved by stimulation in patients with spinal cord injury is typically characterized by adequate count but impaired motility (Brackett et al, 2009). Evidence supports impairment of sexual accessory gland function, a noxious seminal plasma milieu, and immunopathic mechanisms as causative (Brackett et al, 2009).

Stimulation with penile vibratory devices serves as first-line therapy, with electroejaculation used if the former is unsuccessful (Brackett et al, 2009). If electroejaculation does not yield sperm or if other factors prevent its use, surgical extraction is indicated (Brackett et al, 2009).

Structural Sperm Abnormalities

As discussed in the section describing evaluation of sperm morphology, the majority of sperm in fertile men are eccentrically shaped, and associating the typical variation of sperm shape to clinical relevance in a quantifiable manner has proved challenging. Investigators have characterized certain infrequent discrete structural abnormalities with overt clinical manifestations.

Evidence suggests genetic bases and consequences for two rare types of specific sperm head abnormalities, globozoospermia and macrocephaly. In globozoospermia, the majority of the sperm lack acrosomal caps, rendering the heads spheric rather than ovoid. Investigators have associated globozoospermia in humans with mutations in the genes *SPATA16* at chromosome band 3q26.32, *PICK1* at 22q12.3-q13.2, and *DPY19L2* at 12q14.2 (Perrin et al, 2013). Both *SPATA16* and *PICK1* localize to proacrosomal granules that are involved in formation of the acrosome during spermatogenesis (Perrin et al, 2013). It is debatable whether higher rates of aneuploidy are present in patients with globozoospermia or teratozoospermia in general; however, for men in whom nearly all sperm have enlarged heads, multiple tails, and abnormal acrosomes, a very high rate of aneuploidy is found (Machev et al, 2005; Sun et al, 2006). The treatment for globozoospermia is IVF with ICSI; owing to the high rate of aneuploidy in sperm associated with macrocephaly and multiple tails, ICSI is not recommended (Machev et al, 2005; Sun et al, 2006; Perrin et al, 2013).

As discussed in the section describing the ultrastructural assessment of sperm, *primary ciliary dyskinesia* refers to a rare condition in which the microtubular architecture of cilia is disrupted (Boon et al,

2013). Because structures such as the sperm tail share similar microtubular construction with cilia, conditions that affect this architecture frequently result in a variety of other clinical manifestations such as immotile sperm, congenital heart disease, chronic respiratory and otolaryngologic infections, and laterality defects (Ferkol and Leigh, 2012). PCD occurs in 1 in 15,000 to 30,000 live births and is typically inherited in an autosomal recessive manner, with occasional X-linked inheritance reported (Ferkol and Leigh, 2012; Boon et al, 2013). Investigators have associated numerous genetic mutations with PCD, with mutations in dynein axonemal heavy chain 5 (DNAH5) and intermediate chain 1 (DNAI1) accounting for 38% of patients with the condition (Hildebrandt et al, 2011; Zariwala et al, 2011; Davis and Katsanis, 2012; Ferkol and Leigh, 2012; Boon et al, 2013). ICSI may achieve pregnancy in cases of PCD (Peeraer et al, 2004).

Empirical Treatment

Please see the Expert Consult website for details.

KEY POINTS: DIAGNOSES AND THERAPIES

- Klinefelter syndrome, characterized by 47,XXY, is the most commonly identified genetic cause of male infertility. Bodily morphologic features cannot reliably exclude the presence of the condition.
- The clinical evaluation of a man identified with CBAVD includes CFTR assessment of both him and his female partner to determine risk of cystic fibrosis in offspring.
- Severe hypogonadotropic hypogonadism may be associated with anosmia and is treated with gonadotropin replacement. Less severe forms are more common, and patients may respond to antiestrogenic agents or aromatase inhibitors.

In general, empirical treatment falls within two categories: either endocrine or nutraceutical based. The highly variable character of the semen analysis and its probabilistic nature make empirical treatments of male infertility difficult to assess without carefully conducted controlled clinical trials. Unfortunately, few exist. Investigators have reported results of many uncontrolled trials of selective endocrine receptor modulators such as clomiphene or gonadotropins in men, but the few available clinical trials usually do not demonstrate pregnancy rates to be greater than that expected by nature acting alone ([Vandekerckhove et al, 2000](#); [Siddiq and Sigman, 2002](#); [Attia et al, 2007](#)). **Consequently, should endocrine treatment be applied, identified endocrine dysfunction should be first demonstrated.**

Aside from endocrine therapy, nutraceuticals serve as the subject of many published reports, with antioxidant activity a common theme for proposed benefit. A Cochrane collaboration review concluded that results from small randomized controlled trials

supported that for subfertile couples undergoing ART, antioxidant supplementation in subfertile men may increase live birth rates, especially for vitamin E, zinc, and a multivitamin ([Vandekerckhove et al, 2000](#)). Investigators have studied the effects of Coenzyme Q10, or ubiquinone, a component of the mitochondrial electron transport chain, on semen analysis parameters in several small controlled trials, with improvement in sperm density and motility observed compared with placebo ([Balercia et al, 2009](#); [Safarinejad, 2009](#); [Safarinejad et al, 2012](#); [Lafuente et al, 2013](#)). Larger, blinded and randomized controlled trials will be required before definitive recommendations may be made regarding nutraceutical efficacy for improving male reproductive potential. The reproductive medical literature is rife with numerous noncontrolled trials of various nutraceuticals and sperm parameters, but, in general, owing to the highly variable nature of seminal metrics, the effect of regression to the mean prevents assessment of results.

Sperm Retrieval Techniques

Varicocelectomy

Orchiopexy in Adults

Since the 10th edition of this book was published, the indications for and techniques of surgery for male infertility have been significantly refined, resulting in substantially increased success in the management of male-factor infertility. These advances include (1) increasing use of genetic and molecular biologic markers (see Chapters 22 and 24) to better select patients for surgical treatment; (2) improved techniques for microsurgical reconstruction for obstruction; (3) the use of varicocelectomy for enhancement of spermatogenesis in azoospermic or severely oligospermic men (Inci et al, 2013; Kirac et al, 2013), for prevention of future infertility and androgen deficiency in young men, and for treatment of androgen deficiency in men of all ages (Tanrikut et al, 2011); and (4) refined microsurgical techniques for sperm retrieval combined with in vitro fertilization (IVF) with intracytoplasmic sperm injection (ICSI) for men with nonobstructive azoospermia. Even men with nonobstructive azoospermia caused by Klinefelter syndrome, once regarded as hopeless cases, can now father biologic offspring with assisted reproductive techniques (Tournaye et al, 1996; Palermo et al, 1998; Ramasamy et al, 2009).

Use of transrectal high-resolution ultrasound as well as scrotal ultrasound with color flow Doppler has substantially improved our diagnostic and therapeutic abilities. Not only does transrectal ultrasound of the seminal vesicles provide diagnostic information, but ultrasound-guided aspiration of the seminal vesicles allows retrieval of sperm to be used for IVF with ICSI (Jarow, 1996). Power Doppler may allow identification of pockets of sperm production in the testis, which may help guide sperm retrieval in men with nonobstructive azoospermia (Har-Toov et al, 2004; Herwig et al, 2004; Tunc et al, 2005). Experimental use of multiphoton tomography in animals and human tissue has potential to further refine our ability to identify sperm in testes (Najari et al, 2012).

IVF with ICSI has expanded our ability to treat even the most severe forms of male-factor infertility such as unreconstructable reproductive tract obstruction and nonobstructive azoospermia. It is, however, a costly procedure and an intense process for the female partner, with associated risks of complications including ovarian hyperstimulation and multiple gestations, as well as complications of the procedures for oocyte retrieval. Furthermore, because ICSI bypasses all natural biologic barriers, it raises realistic concerns of passing genetic abnormalities to the offspring (Kim et al, 1998; Foresta et al, 2005) and is associated with an increased incidence of birth defects in resultant children (Davies et al, 2012). On the other hand, recent analyses clearly indicate that specific treatments for male-factor infertility, such as microsurgical reconstruction for obstructive azoospermia and varicocelectomy for impaired testis function, in properly selected patients remain the safest

and most cost-effective ways of managing infertile men (Kolettis and Thomas, 1997; Pavlovich and Schlegel, 1997; Marmar et al, 2007; Lee et al, 2008; Smit et al, 2010). Specific treatment aimed at correcting or enhancing male infertility can upgrade a couple from intensive levels of assisted reproduction to simpler methods such as intrauterine insemination (IUI) or even to naturally conceived pregnancies (Samplaski et al, 2013).

For men with unreconstructable obstruction as well as men with nonobstructive azoospermia, surgical retrieval of sperm to achieve fertilization, pregnancy, and live birth with IVF and ICSI is a feasible management option. The development and recent refinement of the various techniques of surgical sperm retrieval, from testes, epididymides, or seminal vesicles, with percutaneous or open surgical approaches, have expanded the armamentarium of urologists treating infertile men. In particular, use of the operating microscope to evaluate and identify individual seminiferous tubules more likely to contain sperm has significantly improved the success of testicular sperm extraction (TESE) (Schlegel, 1999; Dabaja and Schlegel, 2013) while minimizing morbidity significantly (Tsujimura et al, 2002; Ramasamy et al, 2005).

The use of microsurgical techniques has also been extended to varicocelectomy. Varicoceles have long been known to be associated with male infertility and have now clearly been shown to result in progressive, duration-dependent testicular injury (Russell, 1957; Lipshultz and Corriere, 1977; Nagler et al, 1985; Sigman and Jarow, 1997). Furthermore, microsurgical varicocelectomy, previously reserved only for men with oligospermia, has now been applied to men with nonobstructive azoospermia, resulting in induction of spermatogenesis and successful return of sperm to the ejaculate in many patients (Matthews et al, 1998; Kim et al, 1999; Pasqualotto et al, 2003, 2006; Ishikawa et al, 2008; Youssef et al, 2009). Although varicocelectomy has historically been reserved for the treatment of infertile men and varicocele-induced pain, there is an emerging concept of early repair of varicoceles to prevent both future infertility and Leydig cell dysfunction. Substantial evidence has accumulated suggesting that varicocele adversely affects Leydig cell function, resulting in lower serum testosterone levels when compared with age-matched controls without varicocele (Tanrikut et al, 2011). Varicocelectomy can halt and even partially reverse this decline (Castro-Magana et al, 1989; Su et al, 1995; Cayan et al, 1999; Tanrikut et al, 2011). In selected men, varicocelectomy may be an effective treatment for symptomatic, age-related androgen deficiency, a condition increasingly referred to as *andropause* or *testosterone deficiency syndrome* (TDS). Thus, with safer and more effective microsurgical techniques, early varicocelectomy has expanded the urologist's role from that of

salvaging remaining testicular function to that of preventing future infertility and TDS.

When surgery for male infertility is undertaken, only rarely is the life (or death) of the patient at stake. What is at stake when the surgery described in this chapter is undertaken is new life, with the potential for altering not only the quality of a couple's life but the future of our species. The responsibilities assumed by the surgeon in these circumstances demand the utmost in judgment and skill. Many of the procedures described in this chapter are among the most technically demanding in all of urology. Acquisition of the skills required to perform them demands intensive laboratory training in microsurgery and a thorough knowledge of the anatomy and physiology of the male reproductive system. Attempting such surgery only occasionally and without proper training would be doing a terrible disservice to the patient and his partner.

SURGICAL ANATOMY

The scrotal contents are unique in their accessibility for physical examination, imaging modalities, and surgical intervention. The success of surgery for male infertility and scrotal disorders is predicated on selection of the correct operation and the most appropriate surgical approach. The details of the history and careful physical examination followed by confirmatory, judiciously selected laboratory and imaging procedures are presented in Chapter 24. When surgical intervention for diagnostic or therapeutic purposes is indicated, a thorough understanding of the anatomy (see Chapter 21) and physiology (see Chapter 22) of the male reproductive system is requisite for planning and carrying out a surgical procedure with the highest probability of success and lowest morbidity.

The key points of surgical anatomy are discussed in the following sections.

Testicular Blood Supply (Box 25-1)

The main blood supply to the testis is from the testicular (internal spermatic) artery arising directly from the aorta. A second blood supply comes from the artery of the vas deferens (deferential artery), which derives from the hypogastric (internal iliac) artery or the superior vesical artery (also a branch of the hypogastric). The third blood supply, primarily to the tunica vaginalis, but with branches going to the testes, comes from the cremasteric (external spermatic) artery, which derives from the inferior epigastric artery. **The testicular artery is the main blood supply to the testes.** Its diameter exceeds the diameter of the deferential (vasal) artery and the cremasteric artery combined (Raman and Goldstein, 2004). Although the vasal and cremasteric arteries can provide adequate blood

supply to the testes in the event that the testicular artery is ligated, especially in children, **atrophy and/or azoospermia has resulted from testicular artery ligation both in adults and in children.** Experience with the one-stage Fowler-Stephens operation for orchiopepy, in which the testicular artery is intentionally ligated, indicates that 20% to 40% of such testes atrophy, although the rate of atrophy is lower in the staged procedure.

Special attention should be paid to men who have undergone vasectomy, in whom the vasal artery has likely been compromised. In these men, maintaining the integrity of the testicular artery in any future operations, such as varicocelectomy, is critical (Lee et al, 2007b).

Epididymal Blood Supply (see Box 25-1)

The epididymis has a rich blood supply. The superior and the medial epididymal arteries derive from the testicular artery. The blood supply to the cauda (inferior pole) of the epididymis derives from the vasal (deferential) artery. The two main blood supplies to the epididymis, running superiorly and inferiorly, form an extensive interconnection such that if the vasal artery is ligated from previous vasectomy, the blood supply to the epididymis from the testicular artery is more than adequate. In addition, in preparation for vaso-epididymostomy or vasovasostomy, the epididymis can be intentionally dissected off the testis and mobilized to the caput (see the discussion of long-term follow-up, evaluation, and results), with the inferior and medial epididymal arteries intentionally ligated without adverse consequence. **As long as the superior epididymal artery remains intact, the blood supply to the epididymis will be adequate.**

Blood Supply of the Vas Deferens (see Box 25-1)

The vas deferens obtains its blood supply from two sources. The seminal vesical (abdominal) end of the vas derives its blood supply from the deferential (vasal) artery. The testicular end of the vas receives additional blood supply from the inferior epididymal arterial interconnections, which extend onto the vas deferens. The two blood supplies to the vas deferens freely anastomose with each other. **After vasectomy, if the vasal vessels are ligated, the testicular end of the vas receives all of its blood supply from branches of the testicular artery and epididymal artery, whereas the seminal vesical (abdominal) end of the vas receives all of its blood supply from the deferential artery.** The vas deferens receives no blood supply from the surrounding cremaster muscle or from any blood vessels from the spermatic cord. Therefore, if the vas deferens is sectioned or obstructed in two different locations, the intervening segment will fibrose owing to lack of blood supply. **Therefore, two simultaneous vasovasostomies cannot be safely performed on the same vas if the vasal vessels have been interrupted in both locations.**

BOX 25-1 Blood Supply to Testis, Epididymis, and Vas Deferens

TESTIS

Testicular (internal spermatic) artery from aorta (main blood supply)
Deferential artery from internal iliac (hypogastric) artery and superior vesical artery
Cremasteric (external spermatic) artery from inferior epigastric artery

EPIDIDYMIS

Superior epididymal artery derived from testicular artery
Inferior epididymal artery derived from vasal (deferential) artery

VAS DEFERENS

Seminal vesical end: deferential artery
Testicular end: deferential artery and inferior epididymal artery

Anatomy of the Excurrent Ducts

Sperm and testicular fluid exit the testes through 7 to 11 tiny efferent ducts. These ducts become convoluted when they exit the testes and form the caput of the epididymis (see Chapters 21 and 41). At that level, they freely anastomose with one another. They all coalesce at the distal caput to form a single epididymal tubule from the caput-corpus junction all the way to the vas deferens. Therefore, **if the epididymis is accidentally injured or ligated distal to the caput, the entire system on that side will be completely obstructed.** This is an important consideration when performing epididymal surgery or surgery near the epididymis. **Hydrocelectomy** is a common surgical procedure that can result in **iatrogenic injury to the epididymis.** In long-standing large hydroceles, the epididymis is often splayed out and difficult to identify. Use of an operating microscope and transillumination of the hydrocele sac help avoid injury to the epididymis, vas, and testicular blood supply (Dabaja and Goldstein, 2014). **Generous margins from the epididymis should be allowed when performing hydrocelectomy (see Chapter 21 and 41).**

Orchiopexy for torsion can also result in inadvertent injury to the epididymis. A single stitch through an epididymal tubule in the corpus or cauda will result in complete obstruction of that side. Because there are multiple lobules at the levels of the caput, puncture of a single tubule for sperm aspiration can be safely performed at the most proximal region of the caput without significantly compromising the flow of sperm into the corpus. Multiple punctures of many tubules at the caput, or any puncture distal to the caput, however, can cause obstruction (Zhang et al, 2013).

Ejaculatory Ducts

The left and right ejaculatory ducts enter the prostatic urethra at the level of the utricle. Obstruction of ejaculatory ducts can lead to azoospermia. Transurethral resection (TUR) of the ejaculatory ducts (TURED) can relieve the obstruction. TURED should not be considered a benign procedure, as it is occasionally associated with significant morbidity (see the section on TURED). Normally, the ejaculatory ducts contain a valvelike mechanism that prevents reflux of urine into the ejaculatory duct. After TURED, a significant percentage of men develop reflux of urine up the excurrent ductal system (Vazquez-Levin et al, 1994) causing chemical and/or bacterial epididymitis.

TESTIS BIOPSY

Indications

The indications for testis biopsy are detailed in Chapter 24. Briefly, testis biopsy is indicated in azoospermic men with testis of normal size and consistency, palpable vasa deferentia, and normal serum follicle-stimulating hormone (FSH) levels, and a negative serum antisperm antibody assay (Lee et al, 2009). Under these circumstances, biopsy will distinguish obstructive from nonobstructive azoospermia. In men with congenital absence of vasa and normal serum FSH levels, biopsy always reveals spermatogenesis (Goldstein and Schlossberg, 1988) and biopsy is not necessary before definitive sperm aspiration and IVF with ICSI. Diagnostic biopsy should usually be performed bilaterally irrespective of the size discrepancy of the two testes. Good spermatogenesis is sometimes found in small, firm testes, and biopsies of large, healthy testes may reveal maturation arrest.

The ability to achieve pregnancy with only a single testicular sperm has turned biopsy into a potentially therapeutic, as well as diagnostic, procedure. Even men with markedly elevated serum FSH levels and small, soft testes, in whom testicular failure is certain, often harbor rare mature sperm in their testes. These sperm can be extracted using techniques described later in this chapter and used for IVF with intracytoplasmic injection of testicular sperm.

The recently discovered heterogeneity of the testes of men with nonobstructive azoospermia coupled with the ability of testicular sperm to acquire motility (Jow et al, 1993) has resulted in changes in the techniques of testis biopsy. Examination of fresh, unfixed tissue for the presence of sperm with tails and possible motility, and examination of multiple samples if sperm are not found initially, is now recommended. Furthermore, optimal care requires the availability, at the time of biopsy, of an andrology laboratory capable of processing and cryopreserving any sperm found at the time of biopsy.

Open Testis Biopsy: Microsurgical Technique

Open biopsy remains the gold standard because it provides an optimal amount of tissue both for accurate diagnosis and for retrieval of sperm for IVF (Rosenlund et al, 1998; Schlegel, 1999; Dardashti et al, 2000). Open testis biopsy may be performed using either general, spinal, or local anesthetic. Local anesthesia of just the skin and tunics without a cord block is uncomfortable; local anesthesia with spermatic cord block can be effective and comfortable. However, there are limitations to the cord block. In animal studies, the incidence of accidental damage to the testicular artery

during blind cord block is 5% (Goldstein et al, 1983). In addition, if there has been previous scrotal surgery with scar or adhesions and if more extensive dissection and manipulation may be required, I prefer to use general or spinal anesthetic.

The surgeon's goal when performing a testis biopsy is to provide an optimal tissue sample, avoid trauma to the specimen, and avoid injury to the epididymis or testicular blood supply. Open biopsy under magnification (preferably with an operating microscope) satisfies these requirements.

An assistant stretches the scrotal skin tightly over the anterior surface of the surface of the testis and confirms that the epididymis is posterior. Bilateral 1-cm transverse scrotal incisions within the scrotal skin folds provide good exposure with a minimum of scrotal bleeding. Alternatively, a single vertical incision in the median raphe may be used. The incision is carried through the skin and dartos muscle, and the tunica vaginalis is opened. If the anatomy is distorted from previous surgery, the epididymis cannot be clearly palpated posteriorly, or the tunica albuginea cannot be clearly identified, the incision should be enlarged and the testis delivered. The edges of the tunica vaginalis are held open with hemostats, and any bleeding vessels are cauterized. Use of loupes or, better yet, the operating microscope allows ready identification of a spot on the tunica albuginea relatively free of visible surface vessels. The wound should be dry before incision of the tunica albuginea to prevent saturation of the biopsy with blood. A 3- to 4-mm incision is made in the tunica albuginea with a 15-degree microknife (Fig. 25-1A). Small crossing vessels are cauterized with bipolar cautery and divided before excision of a pea-sized sample of seminiferous tubules with razor sharp iris scissors (Fig. 25-1B). When handling testis biopsy material for permanent fixation, avoid crushing tissue in any way (including with forceps) because this may traumatize and distort the testicular architecture. The specimen is then deposited directly into either Bouin, Zenker, or collidine buffered glutaraldehyde solution. Formalin fixation results in distortion of testicular histology and should not be used for testis biopsy. A "touch-prep" is made by blotting the cut surface of the testis several times with a glass slide (Fig. 25-1C) and adding a drop of saline, lactated Ringer solution, or human tubal fluid with IVF medium and a coverslip. Examination under high power using a light microscope with or without phase contrast will reveal the presence of sperm with tails and allow assessment of motility (Fig. 25-1D). If no sperm are found in the touch-prep, a second specimen may be cut for a wet "squash prep." In this case, the specimen is placed on a slide, a drop of saline is added, and the specimen is crushed under a coverslip (Jow et al, 1993). If no sperm are found, the tunica is closed with two or three interrupted sutures of 5-0 Vicryl (Fig. 25-1E), and biopsy of another area is performed through the same skin incision. As described later in this chapter, use of an operating microscope providing 10X to 25X magnification may allow selective sampling of larger seminiferous tubules more likely to contain sperm (Schlegel, 1999). If sperm are identified, the slide as well as additional tissue removed are sent for cryopreservation in the andrology laboratory. The location of the biopsy site where sperm were found is noted and the tunica albuginea is closed with two or three interrupted sutures of 6-0 nylon. This facilitates identification of sites of spermatogenesis for future TESE for IVF with ICSI.

The tunica vaginalis is closed with 5-0 monofilament nonabsorbable suture for hemostasis. Use of a nonabsorbable suture facilitates identification of the biopsy site if sperm were found at that site and subsequent TESE is required at the time of IVF with ICSI. The skin is closed with subcuticular 5-0 Monocryl. The wounds are covered with Bacitracin ointment and a fluff-type dressing secured with a snug scrotal support. Antibiotics are unnecessary.

Percutaneous Testis Biopsy

Percutaneous testis biopsy using the same 14-gauge biopsy gun used for prostatic biopsy is a blind procedure and could result in unintentional injury to either the epididymis or the testicular artery. This technique should not be used when previous surgery

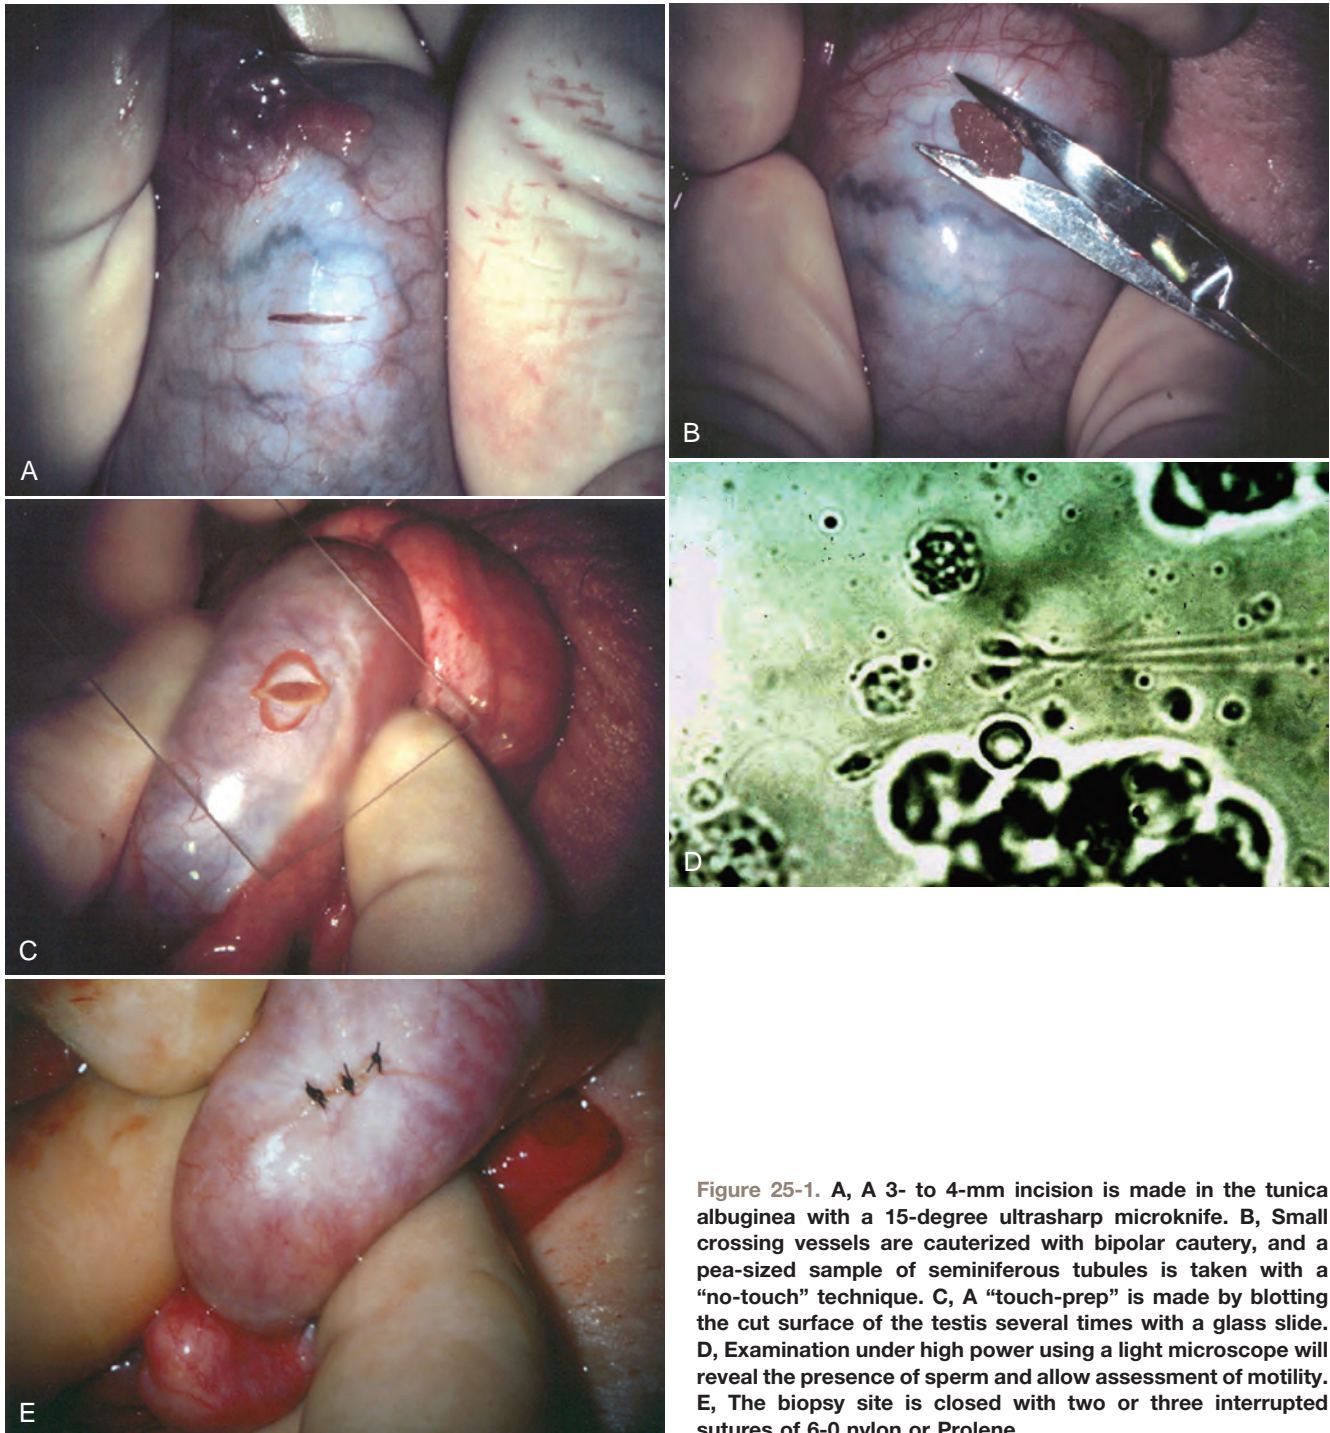

Figure 25-1. A, A 3- to 4-mm incision is made in the tunica albuginea with a 15-degree ultrasharp microknife. B, Small crossing vessels are cauterized with bipolar cautery, and a pea-sized sample of seminiferous tubules is taken with a “no-touch” technique. C, A “touch-prep” is made by blotting the cut surface of the testis several times with a glass slide. D, Examination under high power using a light microscope will reveal the presence of sperm and allow assessment of motility. E, The biopsy site is closed with two or three interrupted sutures of 6-0 nylon or Prolene.

has resulted in scarring and obliteration of normal anatomy. Fine-needle aspiration usually yields specimens that contain few tubules with poorly preserved architecture. When performed with the patient under local anesthesia, a cord block is necessary to minimize pain. The technique of percutaneous biopsy is described later in this chapter. As a therapeutic tool for sperm retrieval, percutaneous biopsy or aspiration is most useful for fresh sperm retrieval for IVF with ICSI in men with obstructive azoospermia and normal spermatogenesis.

Percutaneous Testicular Aspiration

Testicular aspiration performed with a 23-gauge needle or angiocath sheath (Marmar and Benoff, 2005) is probably less invasive

and less painful than percutaneous biopsy but usually yields few tubules with poorly preserved architecture. Although flow cytometric evaluation of this material can distinguish haploid from diploid cells and therefore confirm the presence or absence of late stages of spermatogenesis (Chan et al, 1984), direct wet examination of the aspirate for sperm and assessment of motility provide the most practical clinical information. Three or four aspirations can be performed until sperm are identified. In cases of obstructive azoospermia, these sperm can be used for IVF with ICSI (Craft et al, 1995) when sperm cannot be retrieved from the epididymis (see the section discussing TESE). Fine-needle aspiration has a significantly lower yield of sperm than open microsurgical TESE (micro-TESE) in men with nonobstructive azoospermia.

Complications of Testis Biopsy

Carefully performed, testis biopsy is associated with few complications (Schlegel and Su, 1997; Dardashti et al, 2000). The most serious complication associated with testis biopsy is inadvertent biopsy of the epididymis. If histologic evaluation of the biopsy material reveals epididymis with sperm within the epididymal tubule, obstruction of the epididymis at the site of the biopsy is certain. If, however, there are no sperm within the epididymal tubules, the patient is either obstructed above the level of the epididymal biopsy site or has primary seminiferous tubular failure and no harm has been done.

The most common complication of testis biopsy is hematoma. Hematomas can be quite large and may require drainage. Use of magnification to avoid vessels and bipolar cautery for hemostasis will help prevent this complication. Proper closure of the well-vascularized tunica vaginalis with a continuous 5-0 suture will minimize bleeding and adhesions.

With the rich blood supply of the scrotum and its contents, wound infection is rare in the absence of hematoma, and antibiotics are unnecessary.

VASOGRAPHY

Indications

The absolute indications for vasography are as follows:

1. Azoospermia, plus
2. Complete spermatogenesis with many mature spermatids on testis biopsy, plus
3. At least one palpable vas

Relative indications for vasography are as follows:

1. Severe oligospermia with normal testis biopsy
2. High level of sperm-bound antibodies, which indicates unilateral, bilateral, or partial obstruction (Lee et al, 2009)
3. Low semen volume and very poor sperm motility (partial ejaculatory duct obstruction)

Vasography should answer the following questions:

1. Are there sperm in the vasal fluid?
2. Is the vas obstructed?

If the testis biopsy reveals many sperm, then:

1. Absence of sperm in vasal fluid indicates obstruction on the testicular side of the vasotomy site, most likely an epididymal obstruction. Vasography is done in this case with saline or indigo carmine to confirm patency of the seminal vesical (distal) end of the vas before vasoepididymostomy.

2. Copious vasal fluid containing many sperm indicates vasal or ejaculatory duct obstruction, and formal contrast vasography is performed as described later to document the exact location of the obstruction.
3. Copious thick white fluid without sperm in a dilated vas indicates secondary epididymal obstruction in addition to a potential vasal or ejaculatory duct obstruction.

Vasography with radiographic contrast media and intraoperative radiography is rarely indicated. There is no need to perform vasography at the time of testis biopsy for azoospermia unless immediate reconstruction is planned and the touch or wet prep biopsy reveals mature sperm with tails. If not meticulously performed, vasography can cause stricture or even obstruction at the vasography site, which can complicate subsequent reconstruction (Howards et al, 1975b; Poore et al, 1997). In addition, vasography is of no value in making the diagnosis of epididymal obstruction, and the majority of nonvasectomy related obstructions are epididymal.

If testis biopsy reveals normal spermatogenesis and the vasa are palpable, vasography, if necessary, should be performed only at the time of definitive repair of obstruction. General anesthesia provides the most flexibility for scrotal exploration, vasography, and repair of obstruction. Although local anesthesia can provide adequate analgesia, patients are often unable to lie still through several hours of microsurgery. Long-acting hypobaric spinal or continuous epidural anesthesia can be a satisfactory alternative.

Technique of Vasography and Interpretation of Findings

Inguinal hernia repair, particularly when performed on children, is known to be associated with vasal injury leading to obstruction. If there is no previous inguinal incision and the side of obstruction is unknown, the testis is delivered through a high vertical scrotal incision (see the discussion of surgical scrotal approaches). The vas deferens is identified and isolated at the junction of the straight and convoluted portions of the vas deferens. Using an operating microscope and 10× magnification, the vasal sheath is longitudinally incised and the vasal vessels are carefully preserved (Fig. 25-2A).

A clean segment of bare vas is delivered and surrounded with a vessel loop. A straight clamp is placed beneath the vas to act as a platform. Under 25× magnification, a 15-degree microknife is used to hemitranssect the vas until the lumen is revealed (Fig. 25-2B). Any fluid exuding from the lumen is placed on a slide, mixed with a drop of saline, and sealed with a coverslip for microscopic examination. If the vasal fluid is devoid of sperm with repeated sampling after milking the epididymis and convoluted vas, epididymal

Figure 25-2. A, With use of an operating microscope and 10× magnification, the vasal sheath is longitudinally incised and vasal vessels are carefully preserved. B, Under 25× magnification, a 15-degree microknife is used to hemitranssect the vas until the lumen is revealed.

obstruction is present. The end of the vas toward the seminal vesicles is then cannulated with a 24-gauge angiocatheter sheath and is injected with 1 mL of lactated Ringer solution with a 1-mL tuberculin syringe to confirm its patency (Fig. 25-3). If the Ringer solution passes easily, formal vasography is not necessary. If further proof of patency of the vas deferens is desired, 1 mL of 50% dilute indigo carmine may be injected and the bladder catheterized. The presence of blue-green dye in the urine confirms patency of the vas. Indigo carmine diluted 50/50 with Ringer solution is preferred instead of methylene blue because even at low concentrations methylene blue kills sperm and renders them useless for cryopreservation or for immediate IVF and ICSI (Chang et al, 1998; Sheynkin et al, 1999b; Wood et al, 2003). If motile sperm are found in the vas, the testicular end should be gently barbotaged with 0.2 mL of human tubal fluid medium, and the fluid processed by the andrology laboratory for sperm cryopreservation for potential future use for IVF and ICSI. This should be done before injection with indigo carmine or x-ray contrast material (Sheynkin et al, 1999b).

If a large amount of fluid is found in the vasa lumen and microscopic examination reveals the presence of sperm, the obstruction is toward the seminal vesical end of the vas. In these cases, the vas is usually markedly dilated. A 2-0 Prolene suture can be passed toward the seminal vesical end of the vas and a clamp

placed on the Prolene when the suture passes no further. This is particularly useful for delineating the site of inguinal obstruction from prior groin surgery. If the obstruction is proximal to the inguinal scar, formal vasography is performed by passing a No. 3 whistle-tip ureteral catheter toward the seminal vesical end of the vas. A 16-Fr Foley catheter is placed in the bladder and the balloon is filled with 5 mL of air. Placing the balloon on gentle traction before vasography prevents reflux of contrast into the bladder, which can obscure detail (Fig. 25-4). The air-filled balloon also identifies the location of the bladder neck relative to any obstruction. After the vasa have been cannulated, vasograms are performed with the injection of 0.5 mL of water-soluble contrast media (Fig. 25-5). If vasography reveals obstruction at the site of the ejaculatory ducts (Fig. 25-6), indigo carmine is injected in both vasa to facilitate TURED (see the section on diagnosis of TURED). If both vasa are visualized after injection of contrast into only one vas (Fig. 25-7), it means that both vasa empty into a single cavity, usually a midline ejaculatory duct cyst.

Figure 25-3. The end of the vas toward the seminal vesicles is cannulated with a 24-gauge angiocatheter, and then injected with 1 mL of lactated Ringer solution with a 1-mL tuberculin syringe to confirm its patency.

Figure 25-5. Vasograms are performed with 0.5 mL of water-soluble contrast media.

Figure 25-4. Placing the balloon on gentle traction before vasography prevents reflux of contrast into the bladder, which can obscure detail.

Figure 25-6. Vasography reveals obstruction at the site of the ejaculatory ducts.

Figure 25-7. Both vasa are visualized after injection of contrast into one vas only, revealing distal obstruction.

Figure 25-9. Vasogram demonstrating partial absence of the vas deferens.

Figure 25-8. Vasography reveals a blind-ending vas deferens far from the ejaculatory duct.

Figure 25-10. Vasography reveals an obstruction in the inguinal region.

Vasography may reveal the vas deferens ending blindly, far from the ejaculatory ducts (Fig. 25-8). This finding indicates congenital partial absence of the vas deferens, and these patients should be tested for cystic fibrosis mutations (see Chapter 24). If this is found bilaterally (Fig. 25-9), reconstruction is impossible, but vasal or epididymal sperm can be aspirated into standard laboratory pipettes (see the section on [microsurgical epididymal sperm aspiration techniques](#)) and cryopreserved for future IVF with ICSI. If vasography reveals obstruction in the inguinal region (Fig. 25-10), either inguinal vasovasostomy or crossed transeptal vasovasostomy, using the contralateral unobstructed vas (see the section on [crossed vasovasostomy](#)), may be performed. The hemitranssected vasography sites are carefully closed microsurgically using two or three interrupted

10-0 monofilament nylon sutures for the mucosa and 9-0 for the muscularis and adventitia (see the discussion of the [microsurgical multilayer microdot method](#)).

If the vasal fluid reveals no sperm and vasography confirms patency of the seminal vesical end of the vas, the vas is completely transected, and the seminal vesical end is prepared for vasoepididymostomy (see later). If the vasal fluid reveals many sperm and vasography is normal, then retrograde ejaculation, lack of emission, or aperistalsis of the vas (Tiffany and Goldstein, 1985; Tillem and Mellinger, 1999) is the cause of the azoospermia.

Fine-Needle Vasography

Exposure of the vas in its straight portion may allow vasography to be performed with a fine needle, obviating the need for

hemitranssection of the vas. Dewire and Thomas (1995) used a 30-gauge lymphangiogram needle attached to Silastic tubing. When the sensation of puncture of the lumen is detected, 50% water-soluble contrast is injected to confirm patency radiographically. This has proven to be a difficult technique for even experienced microsurgeons to master. Accurate evaluation of vasal fluid for sperm is difficult because it is so scant. If barbotage with saline or lactated Ringer solution reveals the presence of sperm, then epididymal obstruction has been excluded and contrast can be injected. Collection of vasal sperm for cryopreservation is difficult with this technique. Percutaneous vasography through the scrotal skin has been successfully performed in China (Li, 1980) using the same ringed percutaneous fixation clamp as for the no-scalpel vasectomy. After fixation of the vas beneath the scrotal skin, the vas lumen is punctured with a 22-gauge sharp needle and cannulated with a 24-gauge blunt needle through which vasography is performed. This technique is even more difficult than the direct vision technique with a fine needle.

Complications of Vasography

Stricture

Multiple attempts at percutaneous vasography using sharp needles can result in stricture or obstruction at the vasography site. Imprecise closure of a vasotomy can also result in stricture and obstruction (Howards et al, 1975a; Poore et al, 1997). Use of non-water-soluble contrast agents may also result in stricture, and these agents should not be used for vasography.

Injury to the Vasal Blood Supply

If the vasal blood supply is injured at the site of vasography, vasovasostomy proximal to the vasography site may result in ischemia, necrosis, and obstruction of the intervening segment of vas.

Hematoma

Bipolar cautery should be used for meticulous hemostasis to prevent hematoma in the perivasal sheath.

Sperm Granuloma

Leaky closure of a vasography site may lead to the development of a sperm granuloma, which can result in stricture or obstruction of the vas. The microsurgical technique for closure of vasography sites is identical to that for vasovasostomy described later in this chapter.

Transrectal Vasography and Seminal Vesiculography

If transrectal ultrasound reveals markedly dilated seminal vesicles and/or a midline müllerian duct cyst in a man with obstructive azoospermia, transrectal aspiration followed by instillation of indigo carmine mixed with radiographic contrast is a useful diagnostic maneuver (Jarow, 1994; Katz et al, 1994; Riedenklaus et al, 1995; Eisenberg et al, 2008).

The same bowel preparation and antibiotic coverage used for transrectal prostate biopsy is employed. The fine-needle aspirate is examined for sperm. If sperm are present, it means that at least one vas and epididymis are patent. One-half milliliter of indigo carmine is diluted with 1.5 mL of 50% water-soluble contrast and instilled. If a flat plate reveals a potentially resectable lesion, TURED is performed (see later). Visualization of blue dye effluxing from the ejaculatory ducts or an unroofed cyst aids in determining the adequacy of the resection (Cornel et al, 1999).

This technique obviates the need for formal open scrotal vasography in men with transrectally accessible lesions. If sperm are found in the aspirate, TUR may immediately be undertaken without violating the scrotum. Sperm-laden aspirates may be frozen for future IVF with ICSI if surgery fails.

If no sperm are found in the aspirated fluid, it suggests that secondary epididymal obstruction exists. Simultaneous TURED and vasoepididymostomy is rarely successful. In the face of both ejaculatory duct obstruction and bilateral epididymal obstruction, the best option would be epididymal sperm aspiration for cryopreservation for future IVF and ICSI.

KEY POINTS: VASOGRAPHY

- Perform vasography only if testicular biopsy confirms spermatogenesis consistent with obstructive azoospermia.
- Perform vasography only at the time of planned reconstruction.
- Always sample vasal fluid first to allow cryopreservation of motile sperm if found.
- Use indigo carmine instead of methylene blue to confirm patency.
- Formal vasography with x-ray contrast is needed only to locate obstructions proximal to the internal inguinal ring.
- If transrectal ultrasound reveals dilated seminal vesicles and/or a midline (müllerian duct) cyst, transrectal fine-needle aspiration followed by instillation of contrast and indigo carmine should be performed. If motile sperm are found, they should be cryopreserved.

VASOVASOSTOMY

The number of American men who undergo vasectomy has remained stable at about 500,000 per year, as has the divorce rate of 50%. Surveys suggest that 2% to 6% of vasectomized men will ultimately seek reversal. Furthermore, obstructive azoospermia can be the result of iatrogenic injuries to the vas deferens, usually from hernia repair, in 6% of azoospermic men (Sheynkin et al, 1998a; Shin et al, 2005).

Preoperative Evaluation

Before attempted surgical reconstruction of the reproductive tract, adequate spermatogenesis should be documented. A prior history of natural fertility prevasectomy is usually adequate.

Physical Examination

Testis. Small or soft testes suggest impaired spermatogenesis and predict a poor outcome.

Epididymis. An indurated irregular epididymis often predicts secondary epididymal obstruction, necessitating vasoepididymostomy.

Sperm Granuloma. A sperm granuloma at the testicular end of the vas suggests that sperm have been leaking at the vasectomy site. This vents the high pressures away from the epididymis and is associated with a better prognosis for restored fertility regardless of the time interval since vasectomy (Wosnitzer and Goldstein, 2013).

Vasal Gap. When a very destructive vasectomy has been performed, most of the scrotal straight vas may be absent or fibrotic and the patient should be advised that inguinal extension of the scrotal incision will be necessary to mobilize adequate length of vas to enable a tension-free anastomosis.

Scars from Previous Surgery. Operative scars in the inguinal or scrotal region should alert surgeon to the possibility of iatrogenic inguinal obstruction (hernia repair) or vasal or epididymal obstruction (hydrocelectomy, orchiopexy) (Sheynkin et al, 1998a; Hopps and Goldstein, 2006).

Laboratory Tests

1. Semen analysis with centrifugation and examination of the pellet for sperm should be performed preoperatively.

Complete sperm with tails are found in 10% of preoperative pellets a mean of 10 years after vasectomy (Lemack and Goldstein, 1996). Under these circumstances sperm are certain to be found in the vas on at least one side, indicating a favorable prognosis for restored fertility. Men with a low semen volume should have a transrectal ultrasound to investigate the possibility of an additional ejaculatory duct obstruction.

2. Serum and antisperm antibody studies: The presence of serum antisperm antibodies corroborates the diagnosis of obstruction and the presence of active spermatogenesis (Lee et al, 2009).
3. Serum FSH: Men with small soft testes should have serum FSH measured. An elevated FSH predicts impaired spermatogenesis and a poorer prognosis.
4. Prostate-specific antigen (PSA): Vasectomy reversal candidates over age 40 should have serum PSA measured.

Anesthesia

General anesthesia is preferred. Slight movements are greatly magnified by the operating microscope and disturb performance of the anastomosis. In cooperative patients regional or even local anesthesia with sedation can be used if the vasal ends are easily palpable, a sperm granuloma is present, and/or the time interval since vasectomy is short, decreasing the likelihood of secondary epididymal obstruction. When large vasal gaps are present, extensions of the incisions high into the inguinal canal may be necessary. Furthermore, if vasoepididymostomy is necessary, the operating time could exceed 4 or 5 hours. Local anesthesia limits the options available to the surgeon. Hypobaric spinal anesthesia with long-acting agents such as bupivacaine (Marcaine) can provide 4 to 5 hours of anesthesia time and has the advantage of eliminating lower body motion. Epidural anesthesia with an indwelling catheter can be equally effective.

Surgical Approaches

Scrotal Incision

Bilateral high vertical scrotal incisions provide the most direct access to the obstructed site in cases of vasectomy reversal. Length is usually a problem on the abdominal end but not on the testicular end. Mark the location of the external inguinal ring (Fig. 25-11). If the vasal gap is large or the vasectomy site is high, this incision can easily be extended toward the external ring. If the vasectomy site is low, it is easy to pull up the testicular end. This incision should be made at least 1 cm lateral to the base of the penis. The testis should be delivered with the tunica vaginalis left intact. This provides excellent exposure of the entire scrotal vas deferens and, if necessary, the epididymis.

Figure 25-11. The Xs mark the locations of the external ring. Incisions are marked on the hemiscrotums.

Inguinal Incision

An inguinal incision is the preferred approach in men when obstruction of the inguinal vas deferens from prior herniorrhaphy or orchiopexy is strongly suspected. Incision through the previous scar usually leads directly to the site of obstruction. If the obstruction turns out to be scrotal or epididymal, it is a simple matter to deliver the testis through the inguinal incision or through a separate scrotal incision to perform the anastomosis.

Preparation of the Vasa

The vas is grasped above and below the site of obstruction with two Babcock clamps. Penrose drains replace the Babcock clamps and facilitate the dissection. The vasal vessels and periadventitial sheath are included. Transillumination of the periadventitial sheath by proper adjustment of the operating light allows clear visualization of the blood vessels, which facilitates dissection of the periadventitial sheath and prevents damage to the vasal vessels. The vas is mobilized enough to allow a tension-free anastomosis. To preserve good blood supply the vas should not be stripped of its sheath. The obstructed segment and, if present, sperm granuloma at the vasectomy site should be dissected out and excised. By staying right on the vas and/or sperm granuloma during this dissection, the surgeon reduces the risk of injuring the testicular artery. Injury to adjacent cord structures, especially the testicular artery, is likely to result in testicular atrophy because the vasal artery has usually been interrupted at the vasectomy site.

When large vasal gaps are present, a gauze-wrapped index finger is used to bluntly separate the cord structures from the vas. Blunt finger dissection through the external ring will free the vas to the internal inguinal ring if additional abdominal side length is necessary. These maneuvers will leave all the vasal vessels intact. When the vasal gap is extremely large, additional length can be achieved by dissecting the entire convoluted vas free of its attachments to the epididymal tunica (Fig. 25-12), allowing the testis to drop upside down. These maneuvers can provide an additional 4 to 6 cm of length. To maintain the integrity of the vasal vessels, this dissection is best performed using magnifying loupes or the

Figure 25-12. An additional 4 to 6 cm of length can be obtained by dissecting the epididymis off the testis from the vasoepididymal junction to the caput epididymis.

Figure 25-13. A and B, An additional 4 to 6 cm of length can be obtained by dissecting the epididymis off the testis from the vasoepididymal junction to the caput epididymis.

Figure 25-14. An ultrasharp knife drawn through a slotted 2-, 2.5-, or 3-mm diameter nerve-holding clamp (Accurate Surgical and Scientific Instrument Corp., Westbury, NY) yields a perfect 90-degree cut.

operating microscope under low power. If the amount of vas removed is so large that even these measures fail to allow a tension-free anastomosis, the incision can be extended to the internal inguinal ring, the floor of the inguinal canal cut, and the vas rerouted under the floor, as in a difficult orchiopexy. An additional 4 to 6 cm of length can be obtained by dissecting the epididymis off the testis from the vasoepididymal (VE) junction to the caput epididymis (Fig. 25-13). The superior epididymal vessels are left intact and provide adequate blood supply to the testicular end of the vas. With this combination of maneuvers, up to 10-cm gaps can be bridged.

After the vasa have been freed, the testicular end of the vas is cut transversely. An ultrasharp knife drawn through a slotted 2-, 2.5- or 3-mm diameter nerve-holding clamp (Accurate Surgical and Scientific Instrument Corp., Westbury, NY) yields a perfect 90-degree cut (Fig. 25-14). The cut surface of the testicular end of the vas deferens is inspected under 15× to 25× magnification. A healthy white mucosal ring should be seen and should spring back immediately after gentle dilation. The muscularis should appear smooth and soft. A gritty-looking muscularis layer indicates the presence of scar or fibrotic tissues. The cut surface should look like a bull's eye with the three valsal layers distinctly visible. Healthy bleeding

should be noted from both the cut edge of the mucosa and the surface of the muscularis. If the blood supply is poor or the muscularis is gritty, the vas is recut until healthy tissue is found. The valsal artery and vein are then clamped and ligated with 6-0 nylon. Small bleeders are controlled with microbipolar forceps set at low power. Once a patent lumen has been established on the testicular end, the vas is milked and a clean glass slide is touched to its surface. The valsal fluid is immediately mixed with a drop or two of saline or lactated Ringer solution and preserved under a coverslip for microscope examination. The abdominal end of the vas deferens is prepared in a similar manner and the lumen gently dilated with a microvessel dilator and cannulated with a 24-gauge angiocatheter sheath. Injection of saline or Ringer lactate confirms its patency. After injection of Ringer solution and a test dilation the vas is recut to obtain a fresh surface. **A minimum of instrumentation of the mucosa should be performed.**

After preparation, the ends of the vasa are stabilized with a Microspike approximator clamp (Goldstein, 1985) to remove all tension before the anastomosis is performed. Isolating the field through a slit in a rubber dam prevents microsutures from sticking to the surrounding tissue. A sterile tongue blade covered with a large Penrose drain is placed beneath the ends of the vasa to provide a platform on which to perform the anastomosis.

When to Perform Vasoepididymostomy

The gross appearance of fluid expressed from the testicular end of the vas is usually predictive of findings on microscopic examination (Table 25-1). If microscopic examination of the valsal fluid reveals the presence of sperm with tails, vasovasostomy is performed. If no fluid is found, a 24-gauge angiocatheter sheath is inserted into the lumen of the testicular end of the vas and barbotaged with 0.1 mL of saline while the convoluted vas is vigorously milked. The barbotage fluid is expressed onto a slide and examined. **Men with large sperm granulomas often have virtually no dilation of the testicular end of the vas and little or no fluid initially; however, with barbotage and vigorous milking, invariably sperm can be found in this scant fluid.** If there is no sperm granuloma, and the vas is absolutely dry and spermless after multiple samples have been examined, vasoepididymostomy is indicated. If the fluid expressed from the vas is found to be thick, white, water insoluble, and toothpaste-like in quality, microscope examination rarely reveals sperm. Under these circumstances, the tunica vaginalis is opened and the epididymis inspected. If clear evidence of obstruction is found—that is, an epididymal sperm granuloma with dilated tubules above and collapsed tubules below—vasoepididymostomy is performed. **When in doubt, or if not very experienced with vasoepididymostomy, vasovasostomy should be performed.** However, only 15% of men with bilateral absence of sperm in the

TABLE 25-1 Relationship between Gross Appearance of Vasal Fluid and Microscopic Findings

VASAL FLUID APPEARANCE	MOST COMMON FINDINGS ON MICROSCOPIC EXAMINATION	SURGICAL PROCEDURE INDICATED
Copious, crystal clear, watery	No sperm in fluid	Vasovasostomy
Copious, cloudy thin, water soluble	Usually sperm with tails	Vasovasostomy
Copious, creamy yellow, water soluble	Usually many sperm heads, occasional sperm with short tails	Vasovasostomy
Copious, thick white toothpaste-like, water insoluble	No sperm	Vasoepididymostomy
Scant white thin fluid	No sperm	Vasoepididymostomy
Dry spermless vas; no granuloma at vasectomy site	No sperm	Vasoepididymostomy
Scant fluid, granuloma present at vasectomy site	Barbotage fluid reveals sperm	Vasovasostomy

vasal fluid after barbotage and an intensive search will have sperm return to the ejaculate after vasovasostomy (Sheynkin et al, 2000).

When copious, crystal clear, water-like fluid squirts out from the vas and no sperm are found in this fluid, a vasovasostomy is performed because the likelihood is that sperm will return to the ejaculate after vasovasostomy is performed.

Multiple Vasal Obstructions

If saline injection reveals that the abdominal end of the vas deferens is not patent, a 2-0 nylon or polypropylene suture is gently threaded into the vas lumen to determine the site of obstruction. If the obstruction is within 5 cm of the original vasectomy site, the abdominal end of the vas deferens may be dissected to this site and excised. The incision should then be extended inguinally to free the vas up extensively toward the internal inguinal ring. The testicular end then should also be freed up to the VE junction. If the site of the second obstruction is so far from the vasectomy site that two vasovasostomies are necessary, a single crossed vasovasostomy should be performed to yield one good system (see the section on [crossed vasovasostomy](#)). If this is not possible, vasal or epididymal sperm is aspirated into micropipettes and cryopreserved for future IVF with ICSI (see the section on [sperm retrieval techniques](#)). **Simultaneous vasovasostomies at two separate sites will usually lead to devascularization of the intervening segment with fibrosis and necrosis.**

Varicocelectomy and Vasovasostomy

When men undergoing vasovasostomy or vasoepididymostomy are found to have significant varicoceles on physical examination, it is tempting to repair the varicoceles at the same time. **When varicocelectomy is properly performed, all spermatic veins are ligated and the only remaining avenues for testicular venous return are the vasal veins.** In men who have had vasectomy and are seeking reversal, the vasal veins are likely to be compromised from either the original vasectomy or the reversal itself. Furthermore the integrity of the vasal artery in those men is also likely to be compromised. Varicocelectomy in such men requires preservation of the testicular artery as the primary remaining testicular blood supply as well as preservation of some avenue for venous return.

Microscopic varicocelectomy can ensure preservation of the testicular artery in most cases. Deliberate preservation of small cremasteric or perivasal veins provides venous return. In one series of 570 men seeking vasectomy reversal, 19 had large varicoceles (20 left, 7 bilateral). Microsurgical varicocelectomy was performed at the same time as vasovasostomy. The cremasteric veins and the fine network of veins adherent to the testicular artery were left intact for venous return and to minimize the chances of injury to the testicular artery. Postoperatively, 5 of 26 varicoceles recurred (19%) (Goldstein, 1995). This compares with a recurrence rate of less than 1% in 3500 varicocelectomies I performed in nonvasectomized men in whom the vasal vessels were intact and the cremasteric veins and

periarterial venous network were ligated. However, Mullhall and colleagues performed a series of simultaneous microsurgical vasovasostomies and varicocelectomies without intentionally preserving the cremasteric and periarterial network. They reported a low recurrence rate and no cases of atrophy (Mulhall et al, 1997). It is interesting to note that the increase in recurrences when the cremasteric veins and periarterial venous network were left intact suggests that these veins contribute to a significant proportion of varicocele recurrences.

If varicocelectomy is performed at the same time as vasovasostomy or vasoepididymostomy, it is important that a microscope be used and the testicular artery preserved. Another approach, especially when the female partner is young, is to do the vasovasostomy or vasoepididymostomy first. The semen quality is then assessed postoperatively. **If necessary, varicocelectomy can be safely performed 6 months or more later when venous and arterial channels have formed across the anastomotic line.** This two-stage delayed approach has been completed a dozen times with no atrophy or recurrence.

Anastomotic Techniques: Keys to Success

All successful vasovasostomy techniques depend on adherence to surgical principles that are universally applicable to anastomoses of all tubular structures. These include the following.

1. **Accurate mucosa-to-mucosa approximation**
In human vasovasostomy, the lumen on the testicular side is usually dilated, often to a diameter two to five times that of the abdominal side. Techniques that work well with lumina of equal diameters may be less successful when applied to lumina of markedly discrepant diameters.
2. **Leakproof anastomosis**
Sperm are highly antigenic and provoke an inflammatory reaction when they escape from the normally intact lining of the excurrent ducts of the male reproductive tract. Extravasated sperm adversely influence the success of vasovasostomy (Hagan and Coffey, 1977). Unlike blood vessel anastomoses, in which platelets and clotting factors seal the gaps between sutures, vasal and epididymal fluid contain no platelets or clotting factors, so the water-tightness of the anastomosis is entirely dependent on the mucosal sutures.
3. **Tension-free anastomosis**
When an anastomosis is performed under tension, sperm may appear in the ejaculate for several months after surgery. Ultimately, sperm counts and motility will decrease and azoospermia may ensue. At re-exploration only a thin fibrotic band is found at the anastomotic site. This can be prevented by adequately freeing up the vasa and placing reinforcing sutures in the sheath of the vas.
4. **Good blood supply**
If the cut vas exhibits poor blood supply, it should be recut until healthy bleeding is encountered. If extensive resection is necessary, additional length should be obtained using the techniques previously described.

5. Healthy mucosa and muscularis

If the mucosa or cut surface of the vas exhibits poor distensibility after dilation, peels away from the underlying muscularis, or shreds easily, then the vas should be cut back until healthy mucosa is found. Surgeons should be aware that if needle electrocautery was used in vasectomy, the area of damage to the mucosa and muscularis by the electric current may extend far beyond the tip of the needle cautery. If the muscularis is found to be fibrotic or gritty, the vas must be recut until healthy tissue is found.

6. Good atraumatic anastomotic technique

If multiple surgical errors occur during the procedure, such as inadvertent cutting of the mucosa with the needles when placing sutures, tearing through of sutures, or back-walling of the mucosa, the anastomosis should be resected and redone immediately.

Setup

An operating microscope providing variable magnification from 6× to 32× is used. A diploscope providing identical fields for both surgeon and assistant is preferred. Foot pedal controls for a motorized zoom and focus leave the surgeon's hands free.

Both surgeon and assistant should be comfortably seated on microsurgical chairs that stabilize the chest and arms. This dramatically improves stability and accuracy. An inexpensive alternative is a simple rolling stool with a round bean bag (meditation pillow) taped on top for padding. Two armboards placed on both sides of the surgeon and built up to the appropriate height with folded blankets taped to the boards provide excellent arm support. A right-handed surgeon should sit at the patient's right side so that the forehead stitch is always on the smaller, more difficult abdominal side lumen.

Microsurgical Multilayer Microdot Method

The microsurgical multilayer microdot method of vasovasostomy can handle lumina of markedly discrepant diameters in the straight or convoluted vas. The microdot technique ensures precise suture placement by exact mapping of each planned suture. The microdot method separates the planning from the placement (Goldstein et al, 1998; Dabaja et al, 2013). This allows focus on only one task at a time and results in substantially improved accuracy.

A microtip marking pen (Devon Skin Marker Extra Fine No. 151) is used to map out planned needle exit points. Exactly six mucosal sutures are used for every anastomosis because it is easy to map out and always results in a leakproof closure even when the lumen diameters are markedly discrepant.

Immediately after drying of the cut surface of the testicular end of the vas with a Weck-Cel, a dot is made at the 3 o'clock position halfway between the mucosal ring and the outer edge of the muscle layer. A line is extended out from this dot to serve as a reference point. The second dot is made at the 9 o'clock position, and a line is extended from this dot as well. Additional dots are placed at the 11, 1, 5, and 7 o'clock positions for a total of six. The abdominal end of the vas is marked in the same way to exactly match the testicular end (Fig. 25-15). Monofilament 10-0 nylon sutures, double-armed with 70-micron diameter taper-point needles bent into a fish hook configuration (available from Sharpoint and Ethicon), are used. Double-armed sutures allow inside-out placement (Fig. 25-16), eliminating the need for manipulation of the mucosa and the possibility of back-walling. If the mucosal rings are not sharply defined, the cut surfaces of the vasal ends are stained with indigo carmine to highlight the mucosa (Sheynkin et al, 1999b). The anastomosis is begun with the placement of three 10-0 mucosal sutures anteriorly (Fig. 25-17). The small abdominal side lumen is gently and momentarily dilated with a microvessel dilator just before placement of the sutures. For accurate mucosal approximation, only a small amount of mucosa is included, but one third to one half the muscle wall thickness. Exactly the same amount of tissue is included in the bites on each side. The needle

Figure 25-15. The abdominal end of the vas is marked in the same way to exactly match the testicular end.

Figure 25-16. Double-armed sutures allow inside-out placement.

should exit through the center of each dot. After placement, the three mucosal sutures are tied. Two 9-0 monofilament nylon deep muscularis sutures are placed exactly between the previously placed mucosal sutures, just above but not through the mucosa (Fig. 25-18), and then are tied. These sutures seal the gaps between the mucosal sutures without trauma to the mucosa from the larger 100-micron diameter cutting needle required to penetrate the tough vas muscularis and adventitia. The vas is rotated 180 degrees (Fig. 25-19), and three additional 10-0 sutures are placed through each microdot and then tied to complete the mucosal portion of the anastomosis (Fig. 25-20). Just before the last mucosal suture is tied, the lumen is irrigated with heparinized Ringer solution to prevent the formation of clot in the lumen. After completion of the mucosal layer (Fig. 25-21), four more 9-0 deep muscularis sutures are placed exactly between each mucosal suture, just above but not penetrating the mucosa. Four to six 9-0 nylon interrupted sutures are placed between each muscular suture. This is a purely adventitial layer that covers the underlying mucosal suture. The anastomosis is finished by approximation of the vasal sheath with six to eight interrupted sutures of 8-0 nylon, completely covering the anastomosis and relieving it of all tension (Fig. 25-22).

Anastomosis in the Convoluted Vas

Vasovasostomy performed in the convoluted portion of the vas deferens is technically more demanding than anastomoses in the straight portion. Fear of cutting back into the convoluted vas to obtain healthy tissue may lead surgeons to complete an

Figure 25-17. The anastomosis is begun with the placement of three 10-0 mucosal sutures anteriorly.

Figure 25-18. Place two 9-0 monofilament nylon deep muscularis sutures exactly between the previously placed mucosal sutures, just above but not through the mucosa.

anastomosis in the straight portion when the testicular end of the vas has poor blood supply, unhealthy or friable mucosa, or gritty fibrotic muscularis. Adherence to the following principles will enable anastomosis in the convoluted vas to succeed as often as those in the straight portion.

1. A perfect transverse cut yielding a round ring of mucosa and a lumen directed straight down is essential. A very oblique lumen with a thin flap of muscle and mucosa on one side is not acceptable (Fig. 25-23). The vas should be recut at 0.5-mm intervals until a perfect cut with good blood supply and healthy tissue is obtained. Use of a slotted nerve clamp 2.5 or 3 mm in diameter and an ultrasharp knife facilitates this part of the procedure (see Fig. 25-14). Often the vas must be recut two or three times until a satisfactory cut is obtained.
2. The convoluted vas should not be unraveled. This disturbs the blood supply at the anastomotic line.

Figure 25-19. Rotate the vas 180 degrees, then place three more 10-0 sutures through the remaining microdots.

Figure 25-20. The mucosal layer is complete.

Figure 25-21. Additional sutures are placed between the mucosal sutures, completing the anastomosis.

3. The sheath of the convoluted vas may be carefully dissected free of its attachments to the epididymal tunica (see Fig. 25-12). This will minimize disturbance of its blood supply and provide the necessary length to perform a tension-free anastomosis.

Figure 25-22. Finish the anastomosis by approximating the vasal sheath with six interrupted sutures of 8-0 nylon, completely covering the anastomosis and relieving it of all tension.

Figure 25-23. A very oblique lumen with a thin flap of muscle and mucosa on one side is not acceptable.

4. Care must be taken to avoid taking large bites of the muscularis and adventitial layers on the convoluted side to prevent inadvertent perforation of adjacent convolutions.
5. Reinforce the anastomosis by approximating the vasal sheath of the straight portion to the sheath of the convoluted portion with six interrupted sutures of 7-0 nylon. This will remove all tension from the anastomosis.

Figure 25-24. A crossed vasovasostomy can be done in patients with a unilateral atrophic testis.

Crossed Vasovasostomy

Crossed vasovasostomy is a useful procedure that often provides an easy solution for otherwise difficult problems (Lizza et al, 1985; Hamidinia, 1988; Sheynkin et al, 1998a). Crossover is indicated in the following circumstances:

1. Unilateral inguinal obstruction of the vas deferens associated with an atrophic testis on the contralateral side. A crossover vasovasostomy should be performed to connect a healthy testicle to the contralateral unobstructed vas.
2. Obstruction or aplasia of the inguinal vas or ejaculatory duct on one side and epididymal obstruction on the contralateral side.

It is preferable to perform one anastomosis with a high probability of success (vasovasostomy) than two operations with a much lower chance of success (e.g., unilateral vasaepididymostomy and contralateral TURED).

Technique (Fig. 25-24)

Transect the vas attached to the atrophic testis at the junction of its straight and convoluted portion and confirm its patency with a Ringer or indigo carmine vasogram. Dissect the contralateral vas with the normal testis toward the inguinal obstruction. Clamp and transect it as high up as possible with a right angle clamp. Cross the testicular end of the vas through a capacious opening made in the scrotal septum and proceed with vasovasostomy as described earlier. This procedure is much easier than inguinal vasovasostomy, which requires finding both ends of the vas within the dense scar of a previous inguinal operation.

Transposition of the Testis

Occasionally when vasal length is critically short, a tension-free crossed anastomosis can best be accomplished by testicular transposition (Fig. 25-25). The spermatic cord is always longer than the vas.

Figure 25-25. Occasionally when vasal length is critically short, a tension-free crossed anastomosis can best be accomplished by testicular transposition.

The testes will comfortably cross through a generous opening in the septum and sit nicely in the contralateral scrotal compartment.

Wound Closure

If the vasal dissection was extensive, Penrose drains are brought out the dependent portion of the right and left hemiscrota and fixed in place with sutures and safety pins, preferably before the anastomosis is begun. Placement of drains at the end of the procedure may potentially disturb the anastomosis. The dartos layer is approximated with interrupted 4-0 absorbable sutures and the skin with subcuticular sutures of 5-0 Monocryl. The wound heals with a fine scar. The use of through-and-through skin closures, which give an unacceptable "railroad track" scar, should be avoided. **Virtually all of our procedures are performed on an ambulatory basis.** If drains were placed, the patients are given detailed instructions (with explicit drawings) on how to remove the drains the next morning.

Postoperative Management

Sterile fluff gauze dressings are held in place with a snug-fitting scrotal supporter. Only perioperative antibiotics are used. Patients are discharged with a prescription for acetaminophen with codeine. They shower 48 hours after surgery. **They wear a scrotal supporter at all times (except in the shower), even when sleeping, for 6 weeks postoperatively.** Thereafter, a scrotal supporter is worn during athletic activity until pregnancy is achieved. Desk work is resumed in 3 days. No heavy work or sports are allowed for 3 weeks. **No intercourse or ejaculation is allowed for 3 weeks postoperatively.** Semen analyses are obtained at 1, 3, and 6 months postoperatively and every 6 months thereafter. If azoospermia persists at 6 months, a redo vasovasostomy or vasoepididymostomy will be necessary.

Postoperative Complications

The most common complication is hematoma. In 2500 operations, seven small hematomas occurred. None required surgical

drainage. Most were walnut sized and perivascular. They take 6 to 12 weeks to resolve. Wound infection has not occurred. Late complications include sperm granuloma at the anastomotic site (approximately 5%). This usually is a harbinger of eventual obstruction. Late stricture and obstruction are disappointingly common (see later). **Progressive loss of motility followed by decreasing counts indicates stricture.** Our recent change from Prolene to nylon sutures (Sheynkin et al, 1999a), use of the microdot system to prevent leaks, extensive dissection of the vas until healthy mucosa and muscularis are identified, constant attention to the preservation of good blood supply, and generous use of scrotal support until pregnancy is established have reduced the incidence of late obstruction from 12% (Matthews et al, 1995) to 5% (Kolettis and Thomas, 1997) at 18 months after surgery. Because of the risk of late stricture and obstruction, we strongly encourage cryopreservation of semen specimens as soon as motile sperm appear in the ejaculate.

Long-Term Follow-up Evaluation after Vasovasostomy

When sperm are found in the vasal fluid on at least one side at the time of surgery, the anastomotic technique described results in appearance of sperm in the ejaculate in 99.5% of men (Goldstein et al, 1998; Dabaja et al, 2013). Pregnancy has occurred in 52% of couples followed for at least 2 years and 63% when female factors are excluded, with outcomes dependent on the time since vasectomy and female partner age (Kolettis et al, 2003; Boorjian et al, 2004; Kolettis et al, 2005; Gerrard et al, 2007; Wosnitzer and Goldstein, 2013).

SURGERY OF THE EPIDIDYMIS

Detailed knowledge of epididymal anatomy and physiology (presented in Chapters 21 and 22) is essential before undertaking surgery of this delicate but important structure. Sperm motility and fertilizing capacity progressively increase during passage through the 200-micron diameter, 12- to 15-foot long, tightly coiled single tubule. When the epididymis is obstructed and functionally shortened after vasoepididymostomy, even very short lengths of epididymis are able to adapt and allow some sperm to acquire motility and fertilizing capacity (Silber, 1989a; Jow et al, 1993). Adaptation may gradually continue for up to 2 years after surgical reconstruction, with progressive improvement in the fertility and motility of sperm. Nevertheless, preservation of the greatest possible length of functional epididymis is most likely to result in the best sperm quality after vasoepididymostomy (Schoysman and Bedford, 1986; Schlegel and Goldstein, 1993). Furthermore, because the wall of the epididymis is thinnest in the caput region and gradually thickens, because of the increasing numbers of smooth muscle cells in its more distal (inferior) end, anastomoses are technically easier to perform and more likely to succeed in its distal regions. **Because the corpus and cauda epididymis is a single tubule with a very small diameter, injury or occlusion of a tubule anywhere along its length will lead to total obstruction of outflow at that level.** For these reasons, magnification, with loupes for macrodissection and with the operating microscope for anastomosis, is essential for performing all epididymal surgery.

Fortunately, the epididymis is blessed with a rich blood supply derived from the testicular vessels superiorly and the deferential vessels inferiorly (see the earlier section on **testicular blood supply** and Chapter 21). Because of the extensive interconnections among these branches, either the testicular or deferential branches (but not both) to the epididymis may be divided without compromising epididymal viability.

Conversely, because the epididymal branches of the testicular artery are medial to and separate from the main testicular artery and veins, surgical procedures may be performed on the epididymis without compromise to testicular blood supply.

TABLE 25-2 Comparison of Three Common Techniques for Vasoepididymostomy

TECHNIQUES	ADVANTAGES	DISADVANTAGES
Intussusception (longitudinal intussusception vasoepididymostomy)	Two sutures placed longitudinally in the dilated epididymal tubule provide four points of fixation. Virtually bloodless anastomosis.	Cannot assess tubular fluid for sperm before anastomosis setup.
End-side	Virtually bloodless anastomosis. Epididymal fluid can be examined before anastomosis.	Difficult suture placement to a collapsed tubule.
End-end	Epididymal fluid can be examined before anastomosis. Easy and rapid identification of the level of obstruction in the epididymis. Allows upward mobilization of epididymis to bridge a large vasal gap.	Difficult hemostasis on transected epididymis. Difficult to identify the proper tubule for anastomosis. Difficult outer layer closure. Vasal blood supply from inferior epididymal artery is sacrificed.

Vasoepididymostomy

Before the development of microsurgical techniques, accurate approximation of the vasal lumen to that of a specific epididymal tubule was not possible. Vasoepididymostomy was performed by aligning the vas deferens adjacent to a slash made in multiple epididymal tubules and hoping a fistula would form. Results with this primitive technique were poor. Microsurgical approaches allow accurate approximation of the vasal mucosa to that of a single epididymal tubule (Silber, 1978), resulting in marked improvement in the patency and pregnancy rates (Schlegel and Goldstein, 1993; Chan et al, 2005). Microsurgical vasoepididymostomy, however, is the most technically demanding procedure in all of microsurgery. In virtually no other operation are results so dependent on technical perfection. Microsurgical vasoepididymostomy should be attempted only by microsurgeons who perform the procedure frequently.

Indications

The indications for vasoepididymostomy at the time of vasectomy reversal are reviewed in the earlier section on [vasovasostomy](#). For obstructive azoospermia not caused by vasectomy, vasoepididymostomy is indicated when the testis biopsy reveals complete spermatogenesis and scrotal exploration reveals the absence of sperm in the vasal lumen with no vasal or ejaculatory duct obstruction. The preoperative evaluation is identical to that described earlier for vasovasostomy.

Microsurgical End-to-Side Vasoepididymostomy

End-to-side techniques of vasoepididymostomy have the advantage of being minimally traumatic to the epididymis and relatively bloodless (Table 25-2) (Wagenknecht et al, 1980; Krylov and Borovikov, 1984; Fogdestam et al, 1986; Thomas, 1987; Chan et al, 2005; Schiff et al, 2005). The end-to-side technique does not disturb the epididymal blood supply. When the level of epididymal obstruction is clearly demarcated by the presence of markedly dilated tubules proximally and collapsed tubules distally, the site at which the anastomosis should be performed is readily apparent. The end-to-side approach has the advantage of allowing accurate approximation of the muscularis and adventitia of the vas deferens to a precisely tailored opening in the tunica of the epididymis. This is the preferred technique when vasoepididymostomy is performed simultaneously with inguinal vasovasostomy because it is possible to preserve the vasal blood supply deriving from epididymal branches of the testicular artery (Fig. 25-26). This provides blood supply to the segment of vas intervening between the two anastomoses. Maintenance of the deferential artery's contribution to the testicular blood supply is also important in situations in which the integrity of the testicular artery is in doubt owing to prior surgery

**Figure 25-26.** A diagram of a finished vasoepididymostomy.

such as orchiopexy, nonmicroscopic varicocelectomy, or hernia repair.

The testis is delivered through a 3- to 4-cm high vertical scrotal incision. The vas deferens is identified, isolated with a Babcock clamp, and then surrounded with a Penrose drain at the junction of the straight and convoluted portions of the vas deferens. Under 8× to 15× magnification provided by the operating microscope, the vasal sheath is longitudinally incised with a microknife, and a bare segment of vas stripped of its carefully preserved vessels is delivered. The vas is hemitranssected with the ultrasharp knife until the lumen is entered (Fig. 25-27). The vasal fluid is sampled. If microscopic examination of this fluid reveals the absence of sperm, the diagnosis of epididymal obstruction is confirmed. Patency of the vas and ejaculatory ducts is confirmed by cannulating the abdominal

end of the vas with a 24-gauge angiocatheter sheath and gently injecting lactated Ringer solution with a 1-mL tuberculin syringe (see Fig. 25-3). Further confirmation of patency may be obtained by injecting indigo carmine, catheterizing the bladder, and observing blue-tinged urine. The vas is then completely transected with use of a 2.5-mm slotted nerve clamp (see Fig. 25-27) and the vas is prepared as for vasovasostomy as described earlier.

After the tunica vaginalis has been opened, the epididymis is inspected under the operating microscope. An anastomotic site is selected above the area of suspected obstruction, proximal to any visible sperm granulomas, where dilated epididymal tubules are clearly seen beneath the epididymal tunica (Fig. 25-28). A relatively avascular area is grasped with sharp jeweler's forceps and the epididymal tunica tented upward. A 3- to 4-mm buttonhole is made in the tunica with microscissors to create a round opening that matches the outer diameter of the previously prepared vas deferens. The epididymal tubules are then gently dissected with a

Figure 25-27. The vas is hemitransected with the ultrasharp knife until the lumen is entered.

Figure 25-28. An anastomotic site is selected above the area of suspected obstruction, proximal to any visible sperm granulomas, where dilated epididymal tubules are clearly seen beneath the epididymal tunica.

combination of sharp and blunt dissection until dilated loops of tubule are clearly exposed (Fig. 25-29). If the level of obstruction is not clearly delineated, after the buttonhole opening has been made in the tunic, a 70- μ m diameter tapered needle from the 10-0 nylon microsuture is used to puncture the epididymal tubule beginning as distal as possible; fluid from the puncture site is examined under the 400-power magnification bench microscope. When sperm are found, the puncture sites are sealed with microbipolar forceps, a new buttonhole is made in the epididymal tunic just proximal, and the tubule is prepared as described previously.

The vas deferens is drawn through an opening in the tunica vaginalis and secured in proximity to the anastomotic site with two to four interrupted sutures of 6-0 polypropylene placed through the vasal adventitia and the tunica vaginalis. The vasal lumen should reach the opening in the epididymal tunica easily, with length to spare. The posterior edge of the epididymal tunica is then approximated to the posterior edge of the vas muscularis and adventitia with two to three interrupted sutures of double-armed 9-0 nylon (Fig. 25-30). This is done in such a way as to bring the vasal lumen in close approximation to the epididymal tubule selected for anastomosis.

Classic End-to-Side Technique

Under 25 \times to 32 \times magnification, with use of small curved microscissors or a 15-degree microknife, an opening about 0.3 to 0.5 mm

Figure 25-29. The epididymal tubules are then gently dissected with a combination of sharp and blunt dissection until dilated loops of tubule are clearly exposed.

Figure 25-30. The posterior edge of the epididymal tunica is then approximated to the posterior edge of the vas muscularis and adventitia with two to three interrupted sutures of double-armed 9-0 nylon.

in diameter is made in the selected tubule. Epididymal fluid is touched to a slide, diluted with saline or Ringer solution, and inspected under the microscope for sperm. If no sperm are found, the opening in the tubule is closed with 10-0 sutures, the vas detached, and the tunica incision closed with 9-0 nylon. The procedure is then repeated more proximally in the epididymis.

Once sperm have been identified, they are aspirated into glass capillary tubes and flushed into media for cryopreservation (Fig. 25-31; see the section on the *open tubule technique* later in this chapter) (Matthews et al, 1995). Indigo carmine solution is dripped on the cut tubule to outline the mucosa. Methylene blue kills sperm instantly even when diluted, rendering the sperm useless for cryopreservation (Sheynkin et al, 1999b). Indigo carmine, diluted 50%, is safe for sperm. The posterior mucosal edge of the epididymal tubule is approximated to the posterior edge of the vasal mucosa with two interrupted 10-0 monofilament nylon sutures double-armed with fish hook 70-micron diameter tapered needles (Fig. 25-32). The lumen is irrigated with Ringer solution just before placement of each suture to keep the epididymal lumen open. The lumen is irrigated with heparinized saline just before the last mucosal suture is tied, to prevent clots from obstructing the lumen. Unlike with blood vessels, there are no platelets and fibrinogen to seal a leaky anastomosis and no clot lysis factor to dissolve clots. After these mucosal sutures are tied, the anterior mucosal anastomosis is completed with two to four additional 10-0 sutures.

Figure 25-31. Once sperm have been identified, they are aspirated into glass capillary tubes and flushed into media for cryopreservation.

Figure 25-32. The posterior mucosal edge of the epididymal tubule is approximated to the posterior edge of the vasal mucosa with two interrupted 10-0 monofilament nylon sutures double-armed with fish-hook 70-micron diameter tapered needles.

The outer muscularis and adventitia of the vas are then approximated to the cut edge of the epididymal tunica with 6 to 10 additional interrupted sutures of 9-0 nylon double-armed with 100-micron diameter needles (Fig. 25-33). The vasal sheath is secured to the epididymal tunica with three to five sutures of 9-0 nylon. The testis and epididymis are gently returned to the tunica vaginalis, which is closed with 5-0 Vicryl. Penrose drains are usually not necessary. The scrotum is closed as previously described for vasovasostomy.

Two-Stitch Longitudinal Intussusception Vasoepididymostomy Technique

The original intussusception technique described by Berger (1998) used three double-armed 10-0 sutures placed in the epididymal tubule in a triangular fashion and a 9-0 needle to tear an opening in the middle of the triangle. We now use a two-stitch longitudinal intussusception (LIVE) technique for all vasoepididymostomies.

Figure 25-33. A and B, The outer muscularis and adventitia of the vas are then approximated to the cut edge of the epididymal tunica with 6 to 10 additional interrupted sutures of 9-0 nylon double-armed with 100-micron diameter needles.

Figure 25-34. With this method, four microdots are marked on the cut surface of the vas deferens and two parallel sutures are placed in the distended epididymal tubule longitudinally, but not pulled through.

It is much easier to perform and is even more successful. With this method, four microdots are marked on the cut surface of the vas deferens and two parallel sutures are placed in the distended epididymal tubule longitudinally, but not pulled through (Fig. 25-34). Marmar (2000) suggests mounting two needles in the needle holder and placing them simultaneously transversely in the tubule. However, if the needles are not pulled through to avoid leakage of fluid and tubular collapse, they can be placed one at a time with greater control and accuracy (Chan et al, 2005; Schiff et al, 2005). Longitudinal placement also allows a larger opening to be made in the epididymal tubule without risk of completely transecting it. With a 15-degree microknife, an opening is made exactly between and parallel to the two previously placed sutures. Of note, we have also developed a single-arm technique of vasoepididymostomy that is almost as effective as the double-arm technique (Fig. 25-35) (Monoski et al, 2007). This technique may prove valuable when double-arm sutures are not available.

Technique When Vasal Length Is Severely Compromised (Fig. 25-36)

When there is inadequate length of the vas deferens to reach the dilated epididymal tubule without tension, the epididymis can be dissected down to the VE junction and then dissected off the testes as in the older end-to-end operation.

After the vas has been prepared, the tunica vaginalis is opened and the testis delivered. Inspection of the epididymis under the operating microscope may reveal a clearly delineated site of obstruction. Often, a discrete yellow sperm granuloma is noted, above which the epididymis is indurated and the tubules dilated and below which the epididymis is soft and the tubules collapsed. If the level of obstruction is not clearly delineated, a 70-micron tapered needle from the 10-0 nylon microsuture is used to puncture the epididymal tubule beginning as distal as possible, and fluid is sampled from the puncture site until sperm are found. At that level the puncture is sealed with microbipolar forceps and the epididymis is ligated just proximal to the puncture site with 6-0 nylon. The epididymis is then dissected off the testis and flipped up to obtain additional length. To do this, the epididymis is encircled with a small Penrose drain at the level of obstruction and, under 2.5× loupe magnification, dissected off the testis for 3 to 5 cm, yielding sufficient length to perform the anastomosis. Usually a nice plane can be found between the epididymis and testis, and injury to the epididymal blood supply can be avoided by staying

Figure 25-35. Of note, we have also developed a single-arm technique of vasoepididymostomy that is almost as effective as the double-arm technique.

right on the tunica albuginea of the testis. The inferior and, if necessary, middle epididymal branches of the testicular artery are ligated and divided to free an adequate length of epididymis. The superior epididymal branches entering the epididymis at the caput are always preserved and can provide adequate blood supply to the entire epididymis. The tunica vaginalis is then closed over the testis with 5-0 Vicryl. This prevents drying of the testis and thrombosis of the surface testicular vessels during the anastomosis. The dissected epididymis remains outside the tunica vaginalis.

If the epididymis is indurated and dilated throughout its length, the epididymis is dissected to the VE junction. This dissection is often facilitated by first dissecting the convoluted vas to the VE junction from below and then, after encircling the epididymis with a Penrose drain, dissecting the epididymis to the VE junction from above. In this way the entire VE junction can be freed up. This will allow preservation of maximal epididymal length in cases of distal obstruction near the VE junction. After the epididymis has been dissected off the testis and flipped up, a two-stitch end-to-side intussusception anastomosis is performed as described earlier.

Figure 25-36. In addition, if vasal length is compromised, the epididymis can be dissected to the caput by ligating the inferior and medial epididymal vessels and flipping the epididymis up, providing additional length. A1, A2, B1, B2, C1, and C2 indicate needle exit points.

Long Term Follow-up: Evaluation and Results

Microsurgical vasoepididymostomy in the hands of experienced and skilled microsurgeons will result in the appearance of sperm in the ejaculate in 50% to 85% of men. Patency rates with the intussusception technique can exceed 80% (Berger, 1998; Brandell and Goldstein, 1999; Marmar, 2000). With the classic end-to-side or older end-to-end method, the patency rate is about 70%, and 43% of men with sperm will impregnate their partners after a minimum follow-up of 2 years (Schlegel and Goldstein, 1993; Pasqualotto et al, 1999). With the intussusception technique, patency rates are 70% to 90% (Kolettis and Thomas, 1997; Chan et al, 2005; Schiff et al, 2005). Regardless of technique, pregnancy rates are higher the more distally the anastomosis is performed (Silber, 1989b). With the older end-to-end or end-to-side methods, at 14 months after surgery 25% of initially patent anastomoses have shut down (Matthews et al, 1995). With the intussusception technique, the late shut-down rates appear to be less than 10%, but long-term follow-up with this technique has not been reported. Nevertheless, we recommend banking sperm both intraoperatively (Matthews and Goldstein, 1996) and as soon as they appear in the ejaculate postoperatively after vasoepididymostomy, regardless of technique used. In men with very low counts or poor sperm quality postoperatively and men who remain azoospermic, the sperm intraoperatively cryopreserved can be used for IVF with ICSI. Persistently azoospermic men without cryopreserved sperm can opt for either a redo vasoepididymostomy and/or microscopic epididymal sperm aspiration combined with IVF and ICSI (see the section on sperm retrieval techniques).

TRANSURETHRAL RESECTION OF THE EJACULATORY DUCTS

Ejaculatory duct obstruction is usually a congenital anomaly that represents the opposite end of the spectrum of excurrent ductal system anomalies that begins with congenital complete absence of the vas deferens and most of the epididymis. When the aplastic segment occurs at the terminal end of the vas, where the ejaculatory duct enters the urethra, it is potentially correctable by TUR (Paick et al, 2000; Schroeder-Printzen et al, 2000; Kadioglu et al, 2001; Ozgok et al, 2001; Yurdakul et al, 2008).

Occasionally, ejaculatory duct obstruction results from chronic prostatitis or extrinsic compression of the ejaculatory ducts by prostate or seminal vesical duct cysts (Cornel et al, 1999; Paick et al, 2000; Kadioglu et al, 2001). Higher ejaculatory duct pressures have been directly measured in men with ejaculatory duct obstruction (Eisenberg et al, 2008).

Diagnosis

The work-up leading to the diagnosis of probable ejaculatory duct obstruction is covered in Chapter 24. Briefly, ejaculatory duct obstruction is suspected in azoospermic or severely oligospermic and/or asthenospermic men with at least one palpable vas deferens, a low semen volume, acidic semen pH, and negative, equivocal, or low semen fructose levels. If these men have normal serum levels of FSH and testis biopsy reveals normal spermatogenesis, the diagnosis of ejaculatory duct obstruction is entertained.

Digital rectal examination may reveal a midline cystic structure. Transrectal sonography is key to the diagnosis and treatment of ejaculatory duct obstruction. A midline cystic lesion or dilated ejaculatory ducts and seminal vesicles can be visualized sonographically. As described in the section on transrectal vasography and seminal vesiculography earlier in this chapter, transrectal ultrasound-guided aspiration of the cystic or dilated ejaculatory ducts or seminal vesicles is performed (Jarow, 1994). The aspirate is examined microscopically; if motile sperm are found, they are cryopreserved and 2 to 3 mL of indigo carmine diluted with water-soluble radiographic contrast is instilled. If a radiograph confirms a potentially resectable lesion, TURED is performed without the need for prior vasography because the presence of sperm in the seminal vesicles indicates that at least one epididymis is patent and that the cyst or dilated ejaculatory duct communicates with a nonobstructed vas. The instillation of indigo carmine assists in localizing the opening of the ejaculatory duct and confirms when resection has successfully opened the obstructed system. Transrectal sonography with aspiration should be performed immediately before anticipated surgery and uses the same bowel preparation and antibiotic prophylaxis as for transrectal prostate biopsy.

If no sperm are found in the aspirate, vasography, as described in the earlier section on technique of vasography and interpretation of findings, is necessary. If no sperm are found in either vas when the vasotomy is made and vasography reveals ejaculatory duct obstruction, it is best to abandon attempts at reconstruction and simply perform microsurgical epididymal sperm aspiration and cryopreservation for future IVF and ICSI. Performance of simultaneous vasoepididymostomy and TURED has never worked in my experience. If ejaculatory duct obstruction is confirmed by vasography using a 50% water-soluble contrast medium and sperm are present in the vasa, the 3-Fr whistle tip ureteral vasography stents are left in place so that a dilute indigo carmine solution can be injected by the assistant to aid resection.

Technique

Cold knife incision alone almost always leads to reobstruction. The resectoscope, with the 24-Fr cutting loop, is engaged with a finger placed in the rectum providing anterior displacement of the posterior lobe of the prostate. The ejaculatory ducts course between the bladder neck and the verumontanum and exit at the level of and along the lateral aspect of the verumontanum (Fig. 25-37). Resection of the verumontanum will often reveal the dilated ejaculatory duct orifice or cyst cavity. Resection should be carried out in this region with great care to preserve the bladder neck proximally, the striated sphincter distally, and the rectal mucosa posteriorly. Efflux of indigo carmine from dilated orifices confirms adequate resection. Avoid excessive coagulation. If formal vasography was performed, the hemivasotomies are carefully closed using microsurgical technique. A Foley catheter is left overnight and the patient receives an additional 7 days of oral antibiotics.

Figure 25-37. The ejaculatory ducts course between the bladder neck and the verumontanum and exit at the level of and along the lateral aspect of the verumontanum.

Complications

Reflux

Reflux of urine into the ejaculatory ducts, vas, and seminal vesicles occurs after a majority of resections. This can be documented by voiding cystourethrography or measurement of semen creatinine levels (Malkevich et al, 1994). Contamination of semen by urine impairs sperm quality.

Epididymitis

Reflux can lead to acute and chronic epididymitis. Recurrent epididymitis often results in epididymal obstruction. The incidence of epididymitis after TUR is probably underestimated. Symptomatic chemical epididymitis may occur from refluxing urine. Chronic low-dose antibacterial suppression, such as that used for vesicoureteral reflux, may be necessary until pregnancy is achieved. If epididymitis is chronic and recurrent, vasectomy or even epididymectomy may be necessary.

Retrograde Ejaculation

Even when care has been taken to spare the bladder neck, retrograde ejaculation is common after TUR. Pseudoephedrine 120 mg orally 90 minutes before ejaculation or Ornade Spansules (chlorpheniramine and phenylpropanolamine) twice a day for a week may prevent this. If this is not successful, sperm can be retrieved from alkalized urine and used for either IUI or IVF with ICSI.

Results

TURED results in increased semen volume about two thirds of the time and appearance of sperm in the ejaculate in about 50% of previously azoospermic men. Pregnancy rates are based on case reports and small series (Goldwasser et al, 1985; Paick et al, 2000; Ozgok et al, 2001; Fuse et al, 2003; Yurdakul et al, 2008). If viable sperm appear in the ejaculate but the quality is poor, IVF with ICSI is recommended and currently yields delivery rates of up to 38.5% per attempt. Because of the potential for serious complications, TUR should be performed only in azoospermic men or in severely oligoasthenospermic men and only after the male and female partners have stated they are unwilling to undergo IVF and have been fully apprised of the risks of TUR.

ELECTROEJACULATION

Men with neurologic impairments in sympathetic outflow, such as seen in traumatic spinal cord injury, demyelinating neuropathies (multiple sclerosis), and diabetes after retroperitoneal lymph node dissection, frequently have abnormalities in or absence of seminal emission. Ejaculation can be induced in most of these men, especially those with high spinal cord injury, with vibratory stimulation (Schellam, 1968; Brindley, 1981; Bennett et al, 1987; Brackett et al, 1997; Ohl et al, 1997). For men who do not respond to vibratory stimulation, electroejaculation has proven to be a safe and effective means of obtaining motile sperm suitable for assisted reproduction techniques (IUI, IVF with ICSI).

The procedure is performed with the patient under general anesthesia except for men with a complete spinal cord injury, who do not require anesthesia. In men with a high thoracic spinal cord lesion (above T6) or in men with prior history of autonomic dysreflexia, pretreatment, 15 minutes before the procedure, with 20 mg of sublingual nifedipine is used. These men should have intravenous access and their blood pressure and pulse should be monitored every 2 minutes before, during, and for 20 minutes after electroejaculation. In the event of a sympathetic outflow (autonomic dysreflexia), termination of the procedure should be sufficient to break the response; however, intravenous access allows for delivery of sympatholytic agents should they become necessary.

Before placing the patient in the lateral decubitus position, the bladder is catheterized and emptied. A 12-Fr or 14-Fr Silastic catheter lubricated with a small amount of mineral oil is used because common lubricants are spermicidal. Ten milliliters of buffer (HEPES-BSA) is instilled into the bladder. Before the electroejaculation sequence, a digital rectal examination and anoscopy are performed. A rectal probe with three large horizontal stripes is well lubricated, inserted with the electrodes facing anteriorly, and applied against the posterior aspect of the prostate and seminal vesicles. The probe is connected to a variable output power source which simultaneously records probe temperature through a thermistor in the rectal probe. Electrostimulation is started at 3 to 5 volts and increased in 1-volt increments with each stimulation (Ohl et al, 2001). An assistant records probe temperatures, number of stimulations to full erection, and ejaculation, and collects the ejaculate in a sterile wide mouth plastic container. The number of stimulations and maximum voltage required are variable and the ejaculate may be retrograde. If probe temperature rises rapidly or above 40°C, stimulation is suspended until the temperature falls below 38°C or the probes are changed. At the completion of stimulation, anoscopy is again performed to check for rectal injury. The bladder is recatheterized to obtain any retrograde-ejaculated sperm. The specimens are then delivered to the laboratory for processing. A second electroejaculation sequence can be immediately performed under the same anesthetic to obtain additional sperm.

With this technique, sperm can be recovered in more than 90% of men. Overall pregnancy rates of up to 40% can be achieved after multiple cycles with IUI. Use of IVF with ICSI will yield 50% live delivery rates for a single (albeit costly) procedure if motile sperm are obtained.

SPERM RETRIEVAL TECHNIQUES

Men with congenital absence or bilateral partial aplasia of vas deferens or those with failed or surgically unreconstructable obstructions can now be treated through use of sperm retrieval techniques in conjunction with IVF (Table 25-3) (Temple-Smith et al, 1985; Silber et al, 1990; Schlegel et al, 1994; Craft et al, 1995; Sheynkin et al, 1998b; Janzen et al, 2000; Levine et al, 2003; Qiu et al, 2003; Anger et al, 2004). These techniques are also useful for intraoperative retrieval of sperm during reconstructive procedures such as vasoepididymostomy, which have significant failure rates. The intraoperatively retrieved sperm may be used immediately if the female

TABLE 25-3 Surgical Techniques for Sperm Retrieval

	ADVANTAGES	DISADVANTAGES
MESA (microsurgical epididymal sperm aspiration)	Microsurgical procedure allows lower complication rate. Epididymal sperm has better motility than testicular sperm. Large number of sperm can be harvested for cryopreservation of multiple vials in a single procedure.	Requires anesthesia and microsurgical skills. Not indicated for nonobstructive azoospermia.
PESA (percutaneous epididymal sperm aspiration)	No microsurgical skill required. Local anesthesia. Epididymal sperm has better motility than testicular sperm.	Complications include hematoma, pain, and vascular injury to testes and obstruction of the epididymis. Variable success in obtaining sperm. Smaller quantity of sperm obtained than with MESA. Not indicated for nonobstructive azoospermia.
TESA (testicular sperm aspiration)	No microsurgical skill required. Local anesthesia. Can be used for obstructive azoospermia.	Immature or immotile testicular sperm. Small quantity of sperm obtained. Poor results in nonobstructive azoospermia. Complications include hematoma, pain, and vascular injury to testes and epididymis.
TESE (testicular sperm extraction)	Low complication rate if performed microsurgically. Preferred technique for nonobstructive azoospermia.	Requires anesthesia and microsurgical skills.

partner has been prepared for IVF or may be cryopreserved for a future IVF with ICSI cycle in the event the reconstructive surgery is unsuccessful. Sperm obtained from chronically obstructed systems usually have poor motility and decreased fertilizing capacity. **The use of ICSI combined with IVF is essential regardless of the count and motility of the aspirated sperm.**

Microsurgical Epididymal Sperm Aspiration Techniques

Open Tubule Technique

The technique described here can be used for either intraoperative sperm retrieval at the time of vasoepididymostomy or as an isolated procedure in men with congenital absence of the vas or unreconstructable obstructions (Matthews and Goldstein, 1996; Nudell et al, 1998). A median raphe approach through two small transverse scrotal incisions within the scrotal skin folds is made. After delivery of the testis, the tunica vaginalis is opened and the epididymis inspected under 16× to 25× magnification using the operating microscope. The epididymal tunica is incised over a dilated tubule as described previously for vasoepididymostomy. Meticulous hemostasis is obtained using bipolar cautery. A dilated tubule is isolated and incised with a 15-degree microknife. The fluid is touched to a slide, a drop of human tubal fluid media is added, a coverslip is placed, and the fluid examined. If no sperm are obtained, the epididymal tubule and tunica are closed with 10-0 and 9-0 monofilament nylon sutures, respectively, and an incision is made more proximally in the epididymis or even at the level of the efferent ductules until motile sperm are obtained.

As soon as motile sperm are found, a dry micropipette (5 μ L; Drummond Scientific, Broomall, PA) is placed adjacent to the effluxing epididymal tubule (Fig. 25-38). A standard hematocrit pipette is less satisfactory but can be used if micropipettes are not available. **Sperm are drawn into the micropipette by simple capillary action.** Negative pressure, as is generated by action of an in-line syringe, should not be applied during sperm recovery because this could disrupt the delicate epididymal mucosa. Two micropipettes may be employed simultaneously to increase speed of sperm recovery.

The highest rate of flow is observed immediately after incision of the tubule. Progressively better quality sperm are often found after the initial washout. **Gentle compression of the testis and epididymis enhances flow from the incised tubule.** With patience, 10 to 20 μ L of epididymal fluid can be recovered.

Figure 25-38. As soon as motile sperm are found, a dry micropipette (5 μ L; Drummond Scientific Co., Broomall, PA) is placed adjacent to the effluxing epididymal tubule.

The micropipette is connected to a short (3 to 5 cm) segment of medical grade silicone tubing (American Scientific Products, McGaw Park, IL). Alternatively, the tubing attached to a 25-gauge butterfly needle may be used. A 20-gauge needle fitted to a Luer-tip syringe is then placed in line. The fluid is flushed with IVF medium (0.5 to 1.0 mL) into a sterile container. Once a micropipette has been used, it is discarded. Residual fluid in the pipette will disrupt capillary action. A typical procedure requires 4 to 12 micropipettes. The sperm bank should be instructed to cryopreserve the aspirate in multiple vials (aliquots) so that several IVF cycles may be attempted if required (Janzen et al, 2000; Anger et al, 2004).

Experience with the technique has revealed that, paradoxically, in obstructed systems sperm motility is better more proximal in the epididymis, with the most motile sperm often found in the efferent ductules (Fig. 25-39). Motility immediately after aspiration and consequently fertilization rates are highest in men who have the longest length of epididymal tubule available. Even when packed with debris distally, the epididymal tubule may be capable of secreting substances that can diffuse proximally and benefit sperm motility and fertilizing capacity.

With use of ICSI, ongoing pregnancy or delivery rates exceeding 60% have been achieved with this technique using either

fresh or cryopreserved epididymal sperm (Schlegel et al, 1995; Nudell et al, 1998). Epididymal sperm aspiration can be done electively, with the cryopreserved sperm used for multiple future IVF cycles (Janzen et al, 2000; Anger et al, 2004).

Percutaneous Epididymal Sperm Aspiration

Percutaneous puncture of the epididymis with a fine needle (Fig. 25-40) has been successfully used to obtain sperm and achieve pregnancies (Shrivastav et al, 1994; Craft and Tsigotis, 1995; Levine et al, 2003; Qiu et al, 2003; Lin et al, 2004). The technique is less reliable than open retrieval, and the small quantities of sperm obtained are sometimes inadequate for cryopreservation. Reported pregnancy rates are half those achieved with open techniques (Sheynkin et al, 1998b). It can also potentially obstruct the epididymis in men in whom future vasoepididymostomy is considered. In view of the enormous costs and effort involved in IVF, epididymal sperm retrieval under direct vision is the preferred technique (Zhang et al, 2013).

Figure 25-41. Percutaneous core biopsy; uses the same 14-gauge biopsy gun as prostate biopsy.

Figure 25-42. Percutaneous aspiration (testicular sperm aspiration) with a high-suction glass syringe and a 23-gauge needle. This is the least invasive procedure but requires 10 to 20 passes to obtain an adequate yield.

Testicular Sperm Extraction

The indications for TESE are as follows:

1. Failure to find sperm in the epididymis in the presence of the spermatogenesis or complete absence of the epididymis.
2. Nonobstructive azoospermia (Schlegel et al, 1997; Tsujimura et al, 2002; Ramasamy et al, 2013a, 2013b).
Testicular sperm has been retrieved via one of three techniques:
3. Open microsurgical TESE, preferably with an operating microscope (micro-TESE), which allows retrieval of the largest number of sperm with potential for cryopreservation; this is the best technique in men with nonobstructive azoospermia.
4. Percutaneous core biopsy; uses the same 14-gauge biopsy gun used for prostate biopsy (Fig. 25-41).
5. Percutaneous aspiration (testicular sperm aspiration [TESA]) with a high-suction glass syringe and a 23-gauge needle. This is the least invasive procedure but often requires 10 to 20 passes to obtain an adequate yield (Fig. 25-42) (Rajfer and Binder, 1989; Harrington et al, 1996; Friedler et al, 1997; Sheynkin et al, 1998b; Mercan et al, 2000; Carpi et al, 2005).

The percutaneous methods are most appropriate in men with normal spermatogenesis and obstructive azoospermia when adequate numbers of sperm can be retrieved in a small amount of tissue (Craft et al, 1995). The pros and cons of these three methods are discussed in the section on *testis biopsy*, earlier in this chapter.

Microsurgical Testicular Sperm Extraction

The use of an operating microscope for standard open diagnostic testes biopsy allows identification of an area in the tunica albuginea free of blood vessels (Fig. 25-43), minimizing the risk of injury to testicular blood supply and allowing a relatively blood-free biopsy specimen (Dardashti et al, 2000). Using the microscope for testis biopsy, Schlegel (1999) discovered that in men with nonobstructive azoospermia, some of the tubules were larger than others. The larger tubules are more likely to yield sperm. Previous studies had revealed that testicular biopsy specimens in men with nonobstructive azoospermia display considerable heterogeneity. Examination of permanently fixed biopsy specimens that display heterogeneity reveals that tubules with spermatogenesis are of considerably larger diameter than tubules that are Sertoli cell only. This difference can be readily observed under the operating microscope (Fig. 25-44).

Technique. With the patient under general or regional anesthetic, the testes are exposed through either a single midline median raphe incision or two transverse incisions within the skin lines and between the scrotal blood vessels. The testes is delivered into the wound. The tunica vaginalis is opened and the operating microscope is brought into the field. Under 10× magnification,

Figure 25-43. The use of an operating microscope for standard open diagnostic testes biopsy allows identification of an area in the tunica albuginea free of blood vessels.

an avascular plane is identified on the anterior surface of the tunica albuginea. Using a 15-degree microknife, a generous transverse incision is made between the blood vessels through the tunica albuginea. Small blood vessels that are seen coursing across the incision are coagulated with the microbipolar cautery before they are incised. This yields a blood-free field. The seminiferous tubules are observed. Sertoli cell-only tubules tend to be thin, white, and stringy. Tubules with active spermatogenesis are larger, plumper, and somewhat yellow. With a micro needle holder or microbipolar forceps, the seminiferous tubules are dissected in an attempt to identify larger tubules. If such a tubule is found, sharp curved iris scissors are used to selectively excise these tubules. The sample is placed in human tubal fluid medium, microdissected, and immediately examined by an andrology laboratory technician present in the operating room. After sperm have been found, hemostasis is obtained with the microbipolar cautery. The incision in the tunica albuginea is closed with a 6-0 nylon suture. The testis is returned to the tunica vaginalis, which is closed with a continuous suture of 5-0 Vicryl. If necessary, the opposite testis is explored.

Results. With use of the microdissection technique, sperm have been identified in 50% of men explored. (Schlegel, 1999; Dabaja and Schlegel, 2013). In men in whom sperm are found, a pregnancy rate of 45%, with a live delivery rate of almost 40%, has been achieved at Cornell using IVF with ICSI. The spontaneous abortion rate is 19%. The high rate of spontaneous abortion is probably a result of the increased incidence of chromosomal abnormalities and DNA damage in the sperm of men with nonobstructive azoospermia (Rucker et al, 1998). Even in severe cases of congenital or acquired testicular failure, as in Sertoli cell-only syndrome (Ramasamy et al, 2013a), postchemotherapy azoospermia (Chan et al, 2001), and nonmosaic (47,XXY) Klinefelter syndrome (Palermo et al, 1998; Ramasamy et al, 2009), sperm have been found and pregnancy and live births achieved (Table 25-4).

Postmortem Sperm Retrieval

Postmortem sperm retrieval and cryopreservation (but no pregnancies) were initially reported by Rothman in 1980 and involved removal and mincing of the epididymis. The retrieved sperm can be frozen and subsequently used to attempt to achieve pregnancy. Pregnancy has now been achieved with sperm retrieved postmortem using IVF with ICSI (reviewed in Benshushan and Schenker, 1998; Tash et al, 2003; Dostal et al, 2005).

Retrieval of sperm from the vas can be performed using the technique described for vasectomy (see earlier). Once the vas has

Figure 25-44. Tubules with spermatogenesis are of considerably larger diameter than tubules that are Sertoli cell only. This difference can be readily observed under the operating microscope.

been delivered, a hemivasotomy is made with a 15-degree microknife (as described in the section on [technique of vasography and interpretation of findings](#)). The testicular end of the vas is cannulated with a 22-gauge angiocatheter and the vas irrigated with a 0.2-mL volume of human tubal fluid medium while the convoluted vas and epididymis are massaged.

The ethical appropriateness of such retrieval is the most important issue surrounding its use, and current guidelines require the patient to have given permission for sperm retrieval and use before death ([Trinkoff and Barone, 2013](#)).

VARICOCELECTOMY

Varicocele is by far the most commonly performed operation for the treatment of male infertility. Varicocele is found in approximately 15% of the general population, 35% of men with primary infertility, and 75% to 81% of men with secondary infertility. Animal and human studies have demonstrated that varicocele is associated with a progressive and duration-dependent decline in testicular function ([Russell, 1957](#); [Lipshultz and Corriere, 1977](#); [Nagler et al, 1985](#); [Harrison et al, 1986](#); [Kass and Belman, 1987](#); [Hadziselimovic et al, 1989](#); [Chehval and Purcell, 1992](#); [Gorelick and Goldstein, 1993](#); [Witt and Lipshultz, 1993](#)).

Repair of varicocele will halt any further damage to testicular function ([Kass and Belman, 1987](#); [Gorelick and Goldstein, 1993](#)) and in a large percentage of men will result in improved spermatogenesis ([Dubin and Amelar, 1977](#); [Schlegel and Goldstein, 1992](#); [Marmar et al, 2007](#)) as well as enhanced Leydig cell function ([Su et al, 1995](#); [Tanrikut et al, 2011](#)). The potentially important role of urologists in preventing future infertility and/or androgen deficiency underscores the importance of using a varicocelectomy technique that minimizes the risk of complications and recurrence. [Table 25-5](#) summarizes the pros and cons of various methods of varicocele repair.

TABLE 25-4 Testicular Sperm Extraction Outcomes by Diagnosis

CONDITION	RETRIEVAL
Klinefelter syndrome	68%
AZFc deletions	70%
Sertoli cell only	30%
Postchemotherapy	53%
Cryptorchidism (postorchiopexy)	74%
Maturation arrest	40%
AZFa, AZFb deletions	0%

AZF, azoospermia factor (Y chromosome gene).

Laparoscopic	Yes	12	3-15	Yes
Radiographic	Yes	0	15-25	Yes
Microscopic inguinal or subinguinal	Yes	0	0.5-1.0	No

Scrotal Operations

A variety of surgical approaches have been advocated for varicocelectomy. The earliest recorded attempts at repair of varicocele date to antiquity and involved external clamping of the scrotal skin, including the enlarged veins. In the early 1900s an open scrotal approach was used, involving the mass ligation and excision of the varicose plexus of veins. At the level of the scrotum, however, the pampiniform plexus of veins are intimately entwined with the coiled testicular artery. Therefore, scrotal operations are to be avoided because damage to the arterial supply of the testis frequently results in testicular atrophy and further impairment of spermatogenesis and fertility.

Retroperitoneal Operations

Retroperitoneal repair of varicocele involves incision at the level of the internal inguinal ring ([Fig. 25-45](#)), splitting of the external and internal oblique muscles, and exposure of the internal spermatic artery and vein retroperitoneally near the ureter. This approach has the advantage of isolating the internal spermatic veins proximally, near the point of drainage into the left renal vein. At this level, only one or two large veins are present, and in addition the testicular artery has not yet branched and is often distinctly separate from the internal spermatic veins. Retroperitoneal approaches involve ligation of the fewest number of veins. This approach is still a commonly used method for the repair of varicocele, especially in children.

A disadvantage of a retroperitoneal approach is the high incidence of varicocele recurrence, especially in children and adolescents, when the testicular artery is intentionally preserved.

Figure 25-45. Retroperitoneal repair of varicocele involves incision at the level of the internal inguinal ring.

Recurrence rates after retroperitoneal varicocelectomy are in the range of 15% (Homonnai et al, 1980; Rothman et al, 1981; Watanabe et al, 2005). Failure is usually the result of preservation of the periaarterial plexus of fine veins (venae comitantes) along with the artery. These veins have been shown to communicate with larger internal spermatic veins. If left intact they may dilate and cause recurrence. Less commonly, failure is a result of the presence of parallel inguinal or retroperitoneal collaterals, which may exit the testis and bypass the ligated retroperitoneal veins, rejoining the internal spermatic vein proximal to the site of ligation (Sayfan et al, 1981; Murray et al, 1986). Dilated cremasteric veins (Sayfan et al, 1980) and scrotal collaterals (Kaufman et al, 1983) are also causes of varicocele recurrence and cannot be identified with a retroperitoneal approach. Positive identification and preservation of the 1.0- to 1.5-mm testicular artery via the retroperitoneal approach are difficult, especially in children in whom the artery is small. The operation involves working in a deep hole, and because at this level the internal spermatic vessels cannot be delivered into the wound, they must be dissected and ligated in situ in the retroperitoneum. In addition, the difficulty of positively identifying and preserving lymphatics while using this approach results in postoperative hydrocele formation after 7% to 33% of retroperitoneal operations (Szabo and Kessler, 1984). The incidence of recurrence appears to be higher in children, with rates of 15% to 45% reported in adolescents (Gorenstein et al, 1986; Levitt et al, 1987; Reitelman et al, 1987). Kass reports that recurrence can be markedly reduced in children and adolescents by intentional ligation of the testicular artery (Kass and Marcol, 1992). This ensures ligation of the periaarterial network of fine veins. Although reversal of testicular growth failure has been documented with intentional testicular artery ligation at the time of retroperitoneal repair in children, the effect of artery ligation on subsequent spermatogenesis is uncertain. In adults, bilateral artery ligation has been documented to occasionally cause azoospermia and testicular atrophy. At least, it is inarguable that testicular artery ligation will not enhance testicular function.

Laparoscopic Varicocelectomy

Laparoscopic repair is in essence a retroperitoneal approach, and many of the advantages and disadvantages are similar to those of the open retroperitoneal approach (Donovan and Winfield, 1992; Hagood et al, 1992; Enquist et al, 1994; Hirsch et al, 1998; Riccabona et al, 2003; Watanabe et al, 2005).

With use of the laparoscope, the internal spermatic vessels and vas deferens can be clearly visualized through the laparoscope as they course through the internal inguinal ring. The magnification provided by the laparoscope allows visualization of the testicular artery (Kobori et al, 2013). With experience, the lymphatics may be visualized and preserved as well (Glassberg et al, 2008). With laparoscopic varicocelectomy the internal spermatic veins are ligated at the same level as with the retroperitoneal (Palomo) approach described previously in the section on retroperitoneal operations. Laparoscopic varicocelectomy should allow preservation of the testicular artery in a majority of patients, as well as preservation of lymphatics. The incidence of varicocele recurrence would be expected to be similar to that associated with the open retroperitoneal operations. These recurrences would be the result of collaterals joining the internal spermatic vein near its entrance to the renal vein, or entering the renal vein separately.

Most series of laparoscopic varicocelectomy report a recurrence rate of 2.9% to 4.5% (May et al, 2006; Glassberg et al, 2008; Barroso et al, 2009), but up to 17% in some (Al-Said et al, 2008). An artery ligation but lymphatic-sparing laparoscopic technique has markedly reduced the incidence of postoperative hydrocele formation in children (Glassberg et al, 2008). The potential complications of laparoscopic varicocelectomy (injury to bowel, vessels, or viscera; air embolism; peritonitis) are significantly more serious than those associated with the open techniques. Furthermore, laparoscopic varicocelectomy requires a general anesthetic. The microsurgical techniques described next can be performed with local or regional

anesthesia and use an incision of 2 to 3 cm for unilateral repair. This is often no greater than the sum of incisions used for a laparoscopic approach. Postoperative pain and recovery from the laparoscopic technique are the same as those associated with subinguinal varicocelectomy (Hirsch et al, 1998). In the hands of an experienced laparoscopist, the approach is a reasonable alternative for the repair of bilateral varicoceles (Donovan and Winfield, 1992; Diamond et al, 2009; Mendez-Gallart et al, 2009; Tong et al, 2009.)

Microsurgical Inguinal and Subinguinal Operations: Preferred Approaches

Subinguinal varicocelectomy is currently the most popular approach. It has the advantage of allowing the spermatic cord structures to be pulled up and out of the wound so that the testicular artery, lymphatics, and small periaarterial veins may be more easily identified. In addition, an inguinal or subinguinal approach allows access to external spermatic and even gubernacular veins (Kaufman et al, 1983), which may bypass the spermatic cord and result in recurrence if not ligated. Lastly, an inguinal or subinguinal approach allows access to the testis for biopsy or examination of the epididymis for obstruction or repair of hydrocele (Dabaja and Goldstein, 2014).

Traditional approaches to inguinal varicocelectomy involve a 5-cm incision made over the inguinal canal, opening of the external oblique aponeurosis, and encirclement and delivery of the spermatic cord. The cord is then dissected and all the internal spermatic veins are ligated (Dubin and Amelar, 1977). The vas deferens and its vessels are preserved. An attempt is made to identify and preserve the testicular artery and, if possible, the lymphatics. In addition, the cord is elevated, and any external spermatic veins that are running parallel to the spermatic cord or perforating the floor of the inguinal canal are identified and ligated. Compared with retroperitoneal operations, conventional nonmagnified inguinal approaches lower the incidence of varicocele recurrence but do not alter the incidence of either hydrocele formation or testicular artery injury. Conventional inguinal operations are associated with an incidence of postoperative hydrocele formation varying from 3% to 15% with an average incidence of 7% (Szabo and Kessler, 1984). Analysis of the hydrocele fluid has clearly indicated that hydrocele formation after varicocelectomy is a result of ligation of the lymphatics (Szabo and Kessler, 1984). The incidence of testicular artery injury during nonmagnified inguinal varicocelectomy is unknown. Case reports, however, suggest that this complication may be more common than realized. It can result in testicular atrophy, and if the operation is performed bilaterally, azoospermia may ensue in a previously oligospermic man. Furthermore, Starzl and his transplant group reported a 14% incidence of testicular atrophy and 70% incidence of hydrocele formation when the spermatic cord was divided and only the vas and vasal vessels preserved (Penn et al, 1972).

The introduction of microsurgical technique to varicocelectomy has resulted in a substantial reduction in the incidence of hydrocele formation (Goldstein et al, 1992; Marmar and Kim, 1994; Matthews et al, 1998; Cayan et al, 2000). This is because the lymphatics can be more easily identified and preserved. Furthermore, the use of magnification enhances the ability to identify and preserve the 0.5- to 1.5-mm testicular artery, thus avoiding the complications of atrophy or azoospermia.

Advocates of nonmicrosurgical techniques contend that the deferential (vasal) artery and, if preserved, the cremasteric artery will provide adequate blood supply to the testes to prevent atrophy. However, anatomic studies have shown that the diameter of the testicular artery is greater than the diameter of the deferential artery and cremasteric artery combined (Raman and Goldstein, 2004). The testicular artery is the main blood supply to the testis. Experience with the one-stage Fowler and Stephens orchiopexy, in which the testicular artery is intentionally ligated, reveals that a substantial percentage of such procedures result in an atrophic testis. Also, animal models indicate that artery preservation varicocelectomy

results in improved testicular ultrastructure whereas artery ligation resulted in further deterioration of ultrastructure (Zheng et al, 2008). At the very least, it is inarguable that ligation of the testicular artery is unlikely to enhance testicular function.

Anesthesia

If the testis is delivered as described later, regional or light general anesthesia is preferred. If only the cord is delivered, local anesthesia with a 50%-50% combination of 0.25% bupivacaine and 1% lidocaine is satisfactory with adjunctive intravenous heavy sedation. After infiltration of the skin and subcutaneous tissues the cord is infiltrated before delivery. Blind cord block carries with it a small risk of inadvertent testicular artery injury (Goldstein et al, 1983). A 30-gauge needle should therefore be used for cord block to minimize the risk of injury and hematoma.

Inguinal and Subinguinal Approaches

The introduction of the subinguinal approach, just below the external inguinal ring (Marmar et al, 1985), obviates the necessity for opening any fascial layer and is associated with less pain and a rapid recovery comparable to laparoscopic procedures. At the subinguinal level, however, significantly more veins are encountered, the artery is more often surrounded by a network of tiny veins that must be ligated, and the testicular artery has often divided into two or three branches, making arterial identification and preservation more difficult (Hopps et al, 2003a).

Subinguinally, the arterial pulsations are often dampened by compression on the edge of the external ring, making its identification somewhat more difficult than when the external oblique is opened. Table 25-6 summarizes the criteria for performing the operation inguinally (external oblique opened) versus subinguinally (fascia intact). In general, it is best to use a subinguinal approach in men with a history of any prior inguinal surgery. Under these circumstances the cord is usually stuck to the undersurface of the external oblique, and opening the fascia risks injury to the cord. A subinguinal approach is easier in obese men in whom opening and closing the fascia is difficult through a small incision. A subinguinal approach is easier in men with high, lax, capacious external rings and in men with long cords and low-lying testes. In these men the level of the external ring is fairly proximal to the testis, and opening the fascia will not result in a significant diminution in the number of veins to be ligated or in the branching of the testicular artery.

I recommend always opening the external oblique in prepubertal children without prior inguinal surgery. In children the testicular artery is very small and systemic blood pressure is low, making identification of the artery very difficult in a subinguinal approach. The fascia could also be opened in men with a solitary testis in whom preservation of the artery is critical. Exposure of the cord more proximally (at the inguinal level) allows identification of the artery before it has branched, where clear pulsations are more readily observed.

Consider opening the fascia in men with prior failed subinguinal varicocelectomy to dissect proximal to the prior scarred ligation area. The microdissection will be quicker and easier. A subinguinal operation is significantly more difficult than a high inguinal operation and should be used only by surgeons who perform the operation frequently. Less experienced microsurgeons should start out doing inguinal operations because it is easier. An inguinal operation is used when simultaneous ipsilateral hernia repair is performed.

Before the incision is made the location of the external inguinal ring is determined by invagination of the scrotal skin and is marked. The size of the incision is determined by the size of the testis when delivery of the testis (see later) is planned. Atrophic testes can be delivered through a 2- to 2.5-cm incision. Larger testes require a 3-cm incision. The incision is made within the Langer lines to minimize scarring.

If the decision is made to perform an inguinal operation and thus to open the fascia, the incision is begun at the external ring and extended laterally 2 to 3.5 cm along the Langer lines (Fig. 25-46). If the operation is to be performed subinguinally, the incision is placed in the skin lines right over the external ring (Fig. 25-47).

Figure 25-46. If the decision is made to perform an inguinal operation and thus to open the fascia, the incision is begun at the external ring and extended laterally 2 to 3.5 cm along the Langer lines.

Figure 25-47. If the operation is to be performed subinguinally, the incision is placed in the skin lines just below the external ring.

TABLE 25-6 Indications for Inguinal (External Oblique Opened) Versus Subinguinal (Fascia Intact) Varicocelectomy

INGUINAL	SUBINGUINAL
Prepubertal children	Prior inguinal surgery
Solitary testis	Obesity
Tight, low external ring	Lax, capacious external ring
	High external ring
Short cord, high-lying testis	Long cord with low-lying testis
Less experienced with microsurgical repair	Very experienced with microsurgical repair

The Camper fascia and Scarpa fascia are divided with the electrocautery between the blades of a Crile clamp. The superficial epigastric artery and vein, if encountered, are retracted or alternately may be clamped, divided, and ligated.

If an inguinal approach is selected, the external oblique aponeurosis is cleaned and opened the length of the incision to the external inguinal ring in the direction of its fibers. A 3-0 absorbable suture placed at the apex of the external oblique incision facilitates later closure.

The spermatic cord is grasped with a Babcock clamp and delivered through the wound. The ilioinguinal and genital branches of the genitofemoral nerve are excluded from the cord, which is then surrounded with a large Penrose drain. If a subinguinal incision was made, the Camper and Scarpa fascia are incised as described earlier. An index finger is introduced into the wound and along the cord into the scrotum. The index finger is then hooked under the external inguinal ring, retracting it cephalad. A small Richardson retractor is slid along the back of the index finger and retracted caudad over the cord toward the scrotum (Fig. 25-48). The spermatic cord will be revealed between the index finger and retractor. The assistant grasps the cord with a Babcock clamp and delivers it through the wound. The cord is surrounded with a large Penrose drain.

Dissection of the Cord

The operating microscope is then brought into the field. Under 6× to 10× magnification the external spermatic fascia is opened with a

Figure 25-48. A small Richardson retractor is slid along the back of the index finger and retracted caudad over the cord toward the scrotum.

Bovie electrocautery instrument in the direction of the cremasteric fibers to avoid injury to the cremasteric arteries. A 5-0 Vicryl suture is placed at the apex of the opening to facilitate later closure. The relatively avascular internal spermatic fascia is opened with scissors as high as possible and held open with the straight mosquito forceps (Fig. 25-49). The magnification is increased to 10× to 25× and, after irrigation with 1% papaverine solution, the cord is inspected for the presence of pulsations revealing the location of the testicular artery. Micro-Doppler is extremely useful in identifying arteries (Fig. 25-50). Once the testicular artery has been identified, it is dissected free of all surrounding tissue, tiny veins, and lymphatics, using a fine-tipped nonlocking micro needle holder and microforceps. The artery is encircled with a vessel loop for positive identification and gentle retraction (Fig. 25-51). The suspected artery is tested by elevating the artery with the tips of the micro needle holder until it is completely occluded and then slowly lowering it until a pulsating blush of blood appears just over the needle holder. If the artery is not immediately identified, the cord is carefully dissected beginning with the largest veins. The veins are stripped clean of adherent lymphatics (Fig. 25-52) and the undersides of the largest veins inspected for an adherent artery. In approximately 50% of patients the testicular artery is adherent to the undersurface of a large vein (Beck et al, 1992). All veins within the cord, with the exception of the vasal veins, are doubly ligated either with hemoclips (Fig. 25-53) or by passing two 4-0 silk ligatures, one black and one white, beneath the vein (Fig. 25-54). These are then tied, and the vein is divided. Medium hemoclips are used for veins 5 mm or larger, small auto-hemoclips for veins 1 to 5 mm, and 4-0 silk for veins smaller than 2 mm. The use of an automatic clip applicator (Ligacip small size, Ethicon, Somerville, NJ) significantly reduces operating time. Bipolar cautery can be used for veins smaller than 0.5 mm. The vasal veins are preserved, providing venous return. If the vas deferens is accompanied by dilated veins greater than 2.5 mm in diameter, they are dissected free of the vasal artery and ligated. The vas deferens is always accompanied by two sets of vessels. As long as at least one set of deferential veins remains intact, venous return will be adequate. At the completion of the dissection, the cord is run over the index finger and inspected to verify that all veins have been identified and ligated. Small veins adherent to the testicular artery are dissected free and ligated or, if smaller than 1 mm, cauterized using a bipolar unit with a jeweler's forcep tip, and divided. Cremasteric arteries are found (usually between and adherent to two cremasteric veins) and preserved in at least 90% of patients. Recent studies using power Doppler imaging in men with nonobstructive azoospermia undergoing TESE have found that tubules containing sperm are most likely to be found in areas of the testis with the greatest blood supply. Therefore, logic would dictate that preservation of maximum testicular blood supply, including both testicular and cremasteric arteries, would be

Figure 25-49. A and B, The operating microscope is then brought into the field. Under 4× to 6× magnification, the external and internal spermatic fasciae are opened.

Figure 25-50. Micro-Doppler is extremely useful in identifying arteries.

Figure 25-51. The artery is encircled with a vessel loop for positive identification and gentle retraction.

Figure 25-52. If the artery is not immediately identified, the cord is carefully dissected, beginning with the largest veins. The veins are stripped clean of adherent lymphatics.

beneficial to testicular function. At the completion of the dissection, only the testicular arteries, cremasteric arteries, lymphatics, and vas deferens with its vessels remain (Fig. 25-55). Dissection is not deemed complete until a run through the cord reveals no additional internal or external spermatic veins. Each time a vein is found and ligated, any remaining veins will dilate up.

Figure 25-53. All veins within the cord, with the exception of the vasal veins, are doubly ligated, either with hemoclips or by passing two 4-0 silk ligatures, one black and one white, beneath the vein (see Fig. 25-54).

Figure 25-54. All veins within the cord, with the exception of the vasal veins, are doubly ligated, either with hemoclips (see Fig. 25-53) or by passing two 4-0 silk ligatures, one black and one white, beneath the vein.

Figure 25-55. At the completion of the dissection, only the testicular arteries, cremasteric arteries, lymphatics, and vas deferens with its vessels remain.

Delivery of the Testis

Delivery of the testis through a small inguinal or subinguinal incision guarantees direct visual access to all possible avenues of testicular venous drainage. Delivery of only the cord allows

Figure 25-56. All external spermatic veins are identified and doubly ligated with hemoclips and divided.

access to most external spermatic collaterals but may miss those close to the testis and will not allow access to scrotal or gubernacular collaterals, which have been demonstrated radiographically to be the cause of 10% of recurrent varicoceles (Kaufman et al, 1983). With gentle upward traction on the cord and upward pressure on the testis through the invaginated scrotum, the testis is easily delivered through the wound. All external spermatic veins are identified and doubly ligated with hemoclips and divided (Fig. 25-56). The gubernaculum is inspected for the presence of veins exiting from the tunica vaginalis. These are either cauterized or doubly clipped and divided. **When this step is completed, all testicular venous return must be within the Penrose-surrounded cord.**

Hydroceles are found in 15% of testes associated with varicoceles. As little as 3 mL of hydrocele fluid can significantly alter testicular temperature regulation (Wysock et al, 2009). If a hydrocele is noted when the testis is delivered, it is repaired. Small ones may be treated with excision of a segment of the hydrocele sac and cauterization of the edges. Larger hydroceles are treated with either a bottleneck or excision technique. The temporary high venous pressure immediately after varicocelectomy can make good hemostasis difficult to achieve after excisional hydrocelectomy. Therefore, there should be no hesitation to use a scrotal Penrose drain placed in the dependent portion of the scrotum for 24 hours after combined varicocelectomy and excisional hydrocelectomy. The testis is then returned to the scrotum and the Penrose drain is left beneath the cord structures.

The external oblique aponeurosis, if opened, is reapproximated with continuous suturing using the previously placed 3-0 suture. The Scarpa and Camper fasciae are reapproximated with a single or continuous 3-0 plain catgut suture, and the skin is approximated with a 5-0 monofilament absorbable subcuticular suture reinforced by two or three Steri-Strips (Fig. 25-57). A scrotal supporter is applied and stuffed with fluff-type dressings. The patient is discharged on the day of surgery with a prescription for Tylenol with codeine. Light work may be resumed in 2 or 3 days.

If any large external or gubernacular veins are ligated after delivery of the testis, the cord is again run over the index finger to search for veins that may dilate after gubernacular or external spermatic veins are ligated. The external spermatic fascia is closed with interrupted 5-0 Vicryl, facilitated by the previously placed suture at the apex of the external spermatic fascia.

Radiographic Occlusion Techniques

Intraoperative venography has been used to visualize the venous collaterals, which if left unligated may result in varicocele recurrence (Sayfan et al, 1981; Belgrano et al, 1984; Levitt et al, 1987; Zaontz and Firlit, 1987). Intraoperative venography does reduce the incidence of varicocele recurrence, but the two-dimensional view afforded often does not enable the surgeon to identify the location of all collaterals.

Figure 25-57. Scarpa and Camper fasciae are reapproximated with a single or continuous 3-0 plain catgut suture, and the skin is approximated with a 5-0 monofilament absorbable subcuticular suture, reinforced by two or three Steri-Strips.

Radiographic coil occlusion of the internal spermatic veins has been successfully used for varicoceles (Lima et al, 1978; Walsh and White, 1981; Weissbach et al, 1981). These techniques are performed under a local anesthetic through a small cut-down incision over the femoral vein. The recurrence rate after balloon occlusion was originally 11% and more recently was reportedly as low as 4% (Kaufman et al, 1983; Mitchell et al, 1985; Murray et al, 1986; Matthews et al, 1992). Failure to successfully cannulate small collaterals and external spermatic veins and scrotal collaterals results in recurrence. Venographic placement of a balloon or coil in the internal spermatic vein is successfully accomplished in 75% to 90% of attempts (White et al, 1981; Morag et al, 1984; Winkelbauer et al, 1994; Sivanathan and Abernethy, 2003); therefore a significant number of men undergoing attempted radiographic occlusion will ultimately require a surgical approach. In addition, the radiographic techniques take 1 to 3 hours to perform compared with 25 to 45 minutes for surgical repair. Although rare, serious complications of radiographic balloon or coil occlusion have included migration of the balloon or coil into the renal vein, resulting in loss of a kidney, pulmonary embolization of the coil or balloon (Matthews et al, 1992), femoral vein perforation or thrombosis, and anaphylactic reaction to radiographic contrast medium. Antegrade scrotal sclerotherapy via cannulation of a scrotal vein has been used in Europe (Tauber and Johnsen, 1994; Ficarra et al, 2002; Minucci et al, 2004). The recurrence rate is similar to that of balloon or coil techniques. Long-term follow-up is not available, and the consequence of escape of the sclerosing agent into the renal vein and vena cava is unknown. In addition, the larger the varicocele, the higher the failure and recurrence rate with this technique. We have seen many men referred with late (2 to 5 years) recurrence after radiographic occlusion. On presentation they typically have slow-filling veins that become prominent at the end of the day. Initial cursory physical examination can miss these recurrences. I believe these recurrences are likely the result of recanalization through the coils because, unlike with surgical repair, the veins are not ligated and divided. Although often initially successful, I believe that radiographic occlusion is less durable than microsurgical ligation.

Complications of Varicocelectomy

Hydrocele

Hydrocele formation is the most common complication reported after nonmicroscopic varicocelectomy. The incidence of this complication varies from 3% to 33%, with an average incidence of

about 7%. Analysis of the protein concentration of hydrocele fluid indicates that **hydrocele formation after varicocelectomy is caused by lymphatic obstruction** (Szabo and Kessler, 1984). At least half of postvaricocelectomy hydroceles grow to a size large enough to warrant surgical excision as a result of the discomfort and growth of the hydrocele to a large size. The effect of hydrocele formation on sperm function and fertility is uncertain. It is known that men with varicocele have significantly elevated intratesticular temperatures (Zorgniotti et al, 1979; Goldstein and Eid, 1989), and this appears to be an important pathophysiologic phenomenon mediating the adverse effects of varicocele on fertility (Saypol et al, 1981). The development of a large hydrocele creates an abnormal insulating layer that surrounds the testis. This may impair the efficiency of the counter-current heat exchange mechanism and therefore obviate some of the benefits of varicocelectomy (Wysock et al, 2009).

Use of magnification to identify and preserve lymphatics can virtually eliminate the risk of hydrocele formation after varicocelectomy (Goldstein et al, 1992; Marmar and Kim, 1994; Glassberger et al, 2008). The management of postvaricocelectomy hydrocele is identical to that for other hydroceles (see Chapter 41).

Testicular Artery Injury

The diameter of the testicular artery in humans is 1.0 to 1.5 mm. The testicular artery supplies two thirds of the testicular blood supply, and the vasal and cremasteric arteries the remaining one third (Raman and Goldstein, 2004). Microdissections of the human spermatic cord have revealed that the testicular artery is closely adherent to a large internal spermatic vein in 40% of men. In another 20% of men the testicular artery is surrounded by a network of tiny veins (Beck et al, 1992). During the course of cord dissection for varicocelectomy the artery may go into spasm and even in its uncontracted state is often difficult to positively identify and preserve. **Injury or ligation of the testicular artery carries with it the risk of testicular atrophy and/or impaired spermatogenesis.** Starzl's transplant group (Penn et al, 1972) reported a 14% incidence of frank testicular atrophy when the testicular artery was purposely ligated. The actual incidence of testicular artery ligation during varicocelectomy is unknown, but some studies suggest it is common (Wosnitzer and Roth, 1983). Animal studies have indicated that the risk of testicular atrophy after testicular artery ligation varies from 20% to 100% (MacMahon et al, 1976; Goldstein et al, 1983). In humans, atrophy after artery ligation is probably less likely a result of the contribution of the cremasteric as well as vasal arterial supply (Raman and Goldstein, 2004). **In children the potential for neovascularization and compensatory hypertrophy of the vasal and cremasteric vessels is probably greater than in adults, making atrophy after testicular artery ligation less likely.** Use of magnifying loupes, or preferably an operating microscope and/or a fine-tipped Doppler probe, facilitates identification and preservation of the testicular artery and therefore minimizes the risk of testicular injury. Radiographic balloon or coil occlusion techniques also eliminate this risk.

Varicocele Recurrence

The incidence of varicocele recurrence after surgical repair varies from 0.6% to 45% (Barbalias et al, 1998; Lemack et al, 1998; Cayan et al, 2000; Al-Kandari et al, 2007). Recurrence is more common after repair of pediatric varicoceles. Radiographic studies of recurrent varicoceles visualize periarterial, parallel inguinal, or midretroperitoneal collaterals or, more rarely, transscrotal collaterals (Kaufman et al, 1983). **Retroperitoneal operations miss parallel inguinal and scrotal collaterals.** Nonmagnified inguinal operations have a lower incidence of varicocele recurrence but fail to address the issue of scrotal collaterals or small veins surrounding the testicular artery. The microsurgical approach with delivery of the testis lowers the incidence of varicocele recurrence to less than 1% compared with 9% with use of conventional inguinal techniques (Goldstein et al, 1992; Marmar and Kim, 1994).

Results

Varicocelectomy results in significant improvement in semen analysis in 60% to 80% of men. Reported pregnancy rates after varicocelectomy vary from 20% to 60% (Marmar et al, 2007). A randomized controlled trial of surgery versus no surgery in infertile men with varicoceles revealed a pregnancy rate of 44% at 1 year in the surgery group versus 10% in the control group (Madgar et al, 1995). In our series of 1500 microsurgical operations, 43% of couples had achieved pregnancy at 1 year (Goldstein and Tanrikut, 2006) and 69% at 2 years when couples with female factors were excluded. **Microsurgical varicocelectomy results in return of sperm to the ejaculate in up to 50% of azoospermic men with palpable varicoceles** (Matthews et al, 1998; Kim et al, 1999; Pasqualotto et al, 2006; Lee et al, 2007a; Ishikawa et al, 2008).

The results of varicocelectomy are also related to the size of the varicocele. **Repair of large varicoceles results in a significantly greater improvement in semen quality than repair of small varicoceles** (Steckel et al, 1993; Jarow et al, 1996). In addition, large varicoceles are associated with greater preoperative impairment in semen quality than small varicoceles, and overall pregnancy rates consequently are similar regardless of varicocele size. Some evidence suggests that the younger the patient is at the time of varicocele repair, the greater the improvement after repair and the more likely the testis is to recover from varicocele-induced injury (Kass et al, 1987). Varicocele recurrence, testicular artery ligation, or postvaricocelectomy hydrocele formation are often associated with poor postoperative results. **In infertile men with low serum testosterone levels, microsurgical varicocelectomy alone results in substantial improvement in serum testosterone levels** (Su et al, 1995; Cayan et al, 1999; Younes, 2003; Rosoff et al, 2009; Tanrikut et al, 2011).

Summary

Varicocele is an extremely common entity, present in 15% of the male population. Varicoceles are found in approximately 35% of men with primary infertility but 75% to 81% of men with secondary infertility. Mounting evidence clearly demonstrates that varicocele causes progressive duration-dependent injury to the testis. Larger varicoceles appear to cause more damage than small varicoceles, and, conversely, repair of large varicoceles results in greater improvement of semen quality. **Varicocelectomy can halt the progressive duration-dependent decline in semen quality found in men with varicoceles.** The earlier the age at which varicocele is repaired, the more likely is recovery of spermatogenic function. **Varicocelectomy can also improve Leydig cell function, resulting in increased testosterone levels** (Su et al, 1995; Cayan et al, 1999; Younes, 2003; Tanrikut et al, 2011).

The most common complications after varicocelectomy are hydrocele formation, testicular artery injury, and varicocele persistence or recurrence. **The incidence of these complications can be reduced by using microsurgical techniques, inguinal or subinguinal operations, and exposure of the external spermatic and scrotal veins.** Use of these advanced techniques of varicocelectomy provides a safe, effective approach to elimination of varicocele, preservation of testicular function, and, in a substantial number of men, an increase in semen quality and likelihood of pregnancy, as well as increase in serum testosterone in men with androgen deficiency.

ORCHIOPEXY IN ADULTS

It is well known that cryptorchidism is associated with a high incidence of infertility even when unilateral. Long hot baths and saunas in humans, on a regular basis, have been shown to impair spermatogenesis. Elevated testicular temperature is also thought to be the primary pathophysiologic feature of varicocele (Zorgniotti, 1980; Saypol et al, 1981; Goldstein and Eid, 1989; Wright et al, 1997). Spermatogenesis is exquisitely temperature sensitive. Both

Figure 25-58. Instead of the testes being side by side, an ectopic testis is one behind the other, almost in the perineum.

animal and human studies have shown that artificial elevation of testicular temperature results in impaired spermatogenesis (Shin et al, 1997; Perez-Crespo et al, 2008; Shiraishi et al, 2010). It will also preserve testicular hormonal function. The technique of orchiopexy in adults is identical to that employed for children. Even with a normal contralateral testis, orchiopexy is worthwhile to bring down a unilateral undescended testis to, if possible, a scrotal location where it can be examined. Leydig cell function in undescended testis can be retained. Orchiopexy in adults with bilateral undescended testes can induce spermatogenesis and allow pregnancy (Shin et al, 1997). Even a solitary cryptorchid testis, when properly placed in the scrotum, can provide enough testosterone to obviate the need for hormone replacement. When orchiopexy is performed in adults, regular self-examination and yearly sonography are mandatory.

Retractile or Ectopic Testes in Adults

Retractile testes in boys are usually not surgically repaired if the testes can be manually manipulated to stay down in the scrotum either in the office or under anesthesia. The fate of persistently retractile testis in adults is unknown. A subset of infertile men have retractile testis (Caucci et al, 1997). The semen analyses of these men often demonstrate a typical stressed pattern similar to those of men with varicoceles. These men, however, do not have palpable varicoceles. They all have at least one and frequently both testes that retract out of the scrotum and into the abdomen and remain there for an hour or more a day. In some men these testes remain in the abdomen virtually all the time, except when in a warm shower or under anesthesia. It is likely that these testes will suffer from impaired temperature regulation and impaired spermatogenesis. Scrotal orchiopexy can improve the semen quality and fertility of some of these men. Some men have ectopic testis, in which instead of the testes being side by side, one testis is behind the other (Fig. 25-58), almost in the perineum. This is also likely to elevate testis temperature.

When scrotal orchiopexy is performed for retractile or ectopic testis in adults, a dartos pouch operation should be performed. Simple suture orchiopexy of the tunica albuginea of the testis to the dartos, as is performed sometimes to prevent torsion, will not prevent retraction of these testes into the groin. Creation of a dartos pouch will keep the testis well down in the scrotum and permanently prevent retraction. **This is also the most reliable and safest technique for the prevention of testicular torsion (Redman and Barthold, 1995).**

A 3- to 4-cm transverse incision is made in the low scrotal skin folds overlying the testis. **The incision is kept very superficial, just through the dermis and not into the dartos. A large pouch must be created to accommodate the adult testis.** The place of dissection is above the dartos and just below the skin, which is kept thin.

After a capacious pouch is created, the dartos and underlying tunica vaginalis are vertically incised and the testis delivered. The cremasteric fibers overlying the spermatic cord are divided and ligated to minimize the tendency of the testis to retract. The opening in the dartos is closed around the cord (but not too tightly) to prevent the testis from falling out of the pouch. The cut edge of the everted tunica is approximated to the opening in the dartos with interrupted synthetic monofilament absorbable sutures. This allows placement of the testis in the pouch without the need for fixation sutures in the tunica albuginea (Redman and Barthold, 1995). The skin is closed over the testis with interrupted sutures of 4-0 chromic catgut. This technique obviates the risk of inadvertent injury to and bleeding from the testicular artery, which courses just under the tunica albuginea (Jarow, 1990).

ACKNOWLEDGMENT

I thank Vanessa L. Dudley and Philip Shihua Li, MD, for their immeasurable assistance in the preparation of this manuscript.

“The penis does not obey the order of its master, who tries to erect or shrink it at will. Instead, the penis erects freely while its master is asleep. The penis must be said to have its own mind, by any stretch of the imagination.”

– Leonardo da Vinci

PHYSIOLOGY OF PENILE ERECTION

Historical Aspects

The first description of erectile dysfunction (ED) dates from about 2000 BC and was set down on Egyptian papyrus. Two types were described: natural (“the man is incapable of accomplishing the sex act”) and supernatural (evil charms and spells). Later, Hippocrates reported many cases of male impotence among the rich inhabitants of Scythia and ascribed it to excessive horseback riding. Aristotle stated that three branches of nerves carry spirit and energy to the penis and that erection is produced by the influx of air (Brenot, 1994). His theory was well accepted until Leonardo da Vinci (1504) noted a large amount of blood in the erect penis of hanged men and cast doubt on the concept of the air-filled penis. However, da Vinci’s writings were kept secret until the beginning of the 20th century (Brenot, 1994). Nevertheless, in 1585, in *Ten Books on Surgery* and the *Book of Reproduction*, Ambroise Paré gave an accurate account of penile anatomy and the concept of erection. He described the penis as being composed of concentric coats of nerves, veins, and arteries and of two ligaments (corpora cavernosa), a urinary tract, and four muscles. “When the man becomes inflamed with lust and desire, blood rushes into the male member and causes it to become erect,” Paré wrote. The importance of retaining blood in the penis was stressed by Dionis (1718; quoted by Brenot, 1994), who attributed this to the muscles cramping the veins at the proximal end, and by Hunter (1787), who thought that venous spasm prevented the exit of blood.

Modern investigations of penile hemodynamics began in the 1970s with xenon washout and cavernosography studies in human volunteers exposed to audiovisual sexual stimuli. These studies yielded conflicting results: Shirai and associates (1978) concluded that penile venous flow is increased during erection, but markedly increased arterial flow compensates for this; Wagner (1981) also demonstrated increased arterial flow but concluded that venous drainage is decreased during erection.

Much of the current understanding of erectile physiology was gained in the 1980s and 1990s. In addition to the role of smooth muscle in regulating arterial and venous flow, the three-dimensional structure of the tunica albuginea and its role in venous occlusion were elucidated. An important breakthrough in the understanding

of neural influences was the identification of nitric oxide (NO) as the major neurotransmitter for erection and of phosphodiesterases (PDEs) for detumescence. The role of endothelium and nitric oxide synthase (NOS) in regulating smooth muscle tone and of the intercellular links affected by gap junctions has been uncovered. The importance of ion channels (potassium and calcium) and Rho/Rho-kinase pathways in contraction and relaxation of smooth muscle also has been shown. In regard to pathophysiology, changes in smooth muscle, nerve endings, endothelium, and the fibroelastic framework associated with many diseases have been identified. These developments are discussed in detail in this chapter.

Functional Anatomy of the Penis

The penis is composed of three cylindrical structures: the paired corpora cavernosa and the corpus spongiosum (which houses the urethra), covered by a loose subcutaneous layer and skin. Its flaccid length is controlled by the contractile state of the erectile smooth muscle and the amount of blood in the sinusoids and varies considerably, depending on emotion and outside temperature. In one study, penile length, measured from the pubopenile junction to the meatus, was 8.8 cm flaccid, 12.4 cm stretched, and 12.9 cm erect, with neither age nor the size of the flaccid penis accurately predicting erectile length (Wessells et al, 1996). In another study, Sparling (1997) concluded that about 15% of men have a downward curve during erection, erect angle is below horizontal in one quarter, and shorter erect lengths (from 4.5 to 5.75 inches) occur in 40% of men. Since then, more studies have been reported from several countries (Awwad et al, 2005) (Table 26-1). Regarding penile morphology and erection, one study showed that, during erection, the penile buckling forces are dependent not only on intracavernous pressures but also on penile geometry and erectile tissue properties. The authors concluded that in patients with normal penile hemodynamics but without adequate rigidity, structural causes should be investigated (Udelson et al, 1998).

Tunica Albuginea

The tunica affords great flexibility, rigidity, and tissue strength to the penis (Hsu et al, 1992) (Fig. 26-1). The tunical covering of the corpora cavernosa is a bilayered structure with multiple sublayers. Inner-layer bundles support and contain the cavernous tissue and are oriented circularly. Radiating from this inner layer are intracavernous pillars that act as struts to augment the septum and provide essential support to the erectile tissue. Outer-layer bundles are oriented longitudinally, extending from the glans penis to the proximal crura; they insert into the inferior pubic rami but are absent between the 5 o’clock and the 7 o’clock positions. Less abundant are oblique-oriented fibers that connect the two main layers. In contrast, the corpus spongiosum lacks an

Figure 26-1. Artist's cross-sectional drawing of the penis, depicting the inner circular and outer longitudinal layers of the tunica albuginea and the intracavernous pillars. The longitudinal layer is absent in the ventral groove housing the corpus spongiosum. (From Lue TF, Akkus E, Kour NW. *Physiology of erectile function and dysfunction*. Campbell's Urology Update 1994;12:1-10.)

outer layer or intracorporeal struts, ensuring a low-pressure structure during erection.

The tunica is composed of elastic fibers that form an irregular, latticed network on which the collagen fibers rest (Fig. 26-2). The detailed histologic composition of the tunica varies with anatomic location and function. Emissary veins run between the inner and outer layers of the tunica for a short distance, often piercing the outer bundles obliquely. However, the cavernous artery and the branches of the dorsal artery that give additional blood supply to the corpus cavernosum take a more direct route and are surrounded by a periarterial soft-tissue sheath, which protects the arteries from occlusion by the tunica albuginea during erection.

The outer tunical layer appears to play an additional role in compression of the emissary veins during erection. It also determines, to a large extent, the variability in tunical thickness and strength (Hsu et al, 1992). Between the 6 o'clock and 7 o'clock positions, the tunical thickness is 0.8 ± 0.1 mm; at the 9 o'clock

Figure 26-2. Micrograph of the human tunica albuginea, showing the interwoven elastic fibers and the finer collagen fibers (Hart stain $\times 100$).

position, 1.2 ± 0.2 mm; and at the 11 o'clock position, 2.2 ± 0.4 mm. At the 3 o'clock, 5 o'clock to 6 o'clock, and 1 o'clock positions, the measurements are nearly identical in mirror-image fashion. (Differences at specific locations have been found to be statistically significant.)

The stress on the tunica before penetration of a test object has been measured as $1.6 \pm 0.2 \times 10^7$ N/m² between the 6 o'clock and 7 o'clock positions, $3.0 \pm 0.3 \times 10^7$ N/m² at the 9 o'clock position, and $4.5 \pm 0.5 \times 10^7$ N/m² at the 11 o'clock position. The strength and thickness of the tunica correlate in a statistically significant fashion with location. The most vulnerable area is located on the ventral groove (between the 5 o'clock and 7 o'clock positions), where the longitudinal outer layer is absent; most prostheses tend to extrude here (Hsu et al, 1994).

The tunica albuginea is composed of fibrillar collagen (mostly type I but also type III) in organized arrays interlaced with elastin fibers. Although collagen has a greater tensile strength than steel, it is unyielding. In contrast, elastin can be stretched up to 150% of its length. The elastin content allows tunical expansion and helps to determine stretched penile length.

External penile support consists of two ligamentous structures: the fundiform and suspensory ligaments. The fundiform ligament arises from Colles fascia and is lateral, superficial, and not adherent to the tunica albuginea of the corpora cavernosa. The suspensory ligament arises from Buck fascia and consists of two lateral bundles and one median bundle, which circumscribe the dorsal vein of the penis. Its main function is to attach the tunica

albuginea of the corpora cavernosa to the pubis, and it provides support for the mobile portion of the penis (Hoznek et al, 1998). In patients with congenital deficiency or in whom this ligament has been severed in “penile elongation” surgery, the erect penis may be unstable or droop.

Corpora Cavernosa, Corpus Spongiosum, and Glans Penis

The corpora cavernosa comprise two spongy, paired cylinders contained in the thick envelope of the tunica albuginea. Their proximal ends, the crura, originate at the undersurface of the puboischial rami as two separate structures but merge under the pubic arch and remain attached up to the glans. The septum between the two corpora cavernosa is incomplete in men but is complete in some species such as dogs.

The corpora cavernosa are supported by a fibrous skeleton that includes the tunica albuginea, the septum, the intracavernous pillars, the intracavernous fibrous framework, and the periarterial and perineural fibrous sheath (Goldstein and Padma-Nathan, 1990; Hsu et al, 1992). Within the tunica are the interconnected sinusoids separated by smooth muscle trabeculae surrounded by elastic fibers, collagen, and loose areolar tissue. The terminal cavernous nerves and helicine arteries are intimately associated with the smooth muscle. Each corpus cavernosum is a conglomeration of sinusoids, larger in the center and smaller in the periphery. In the flaccid state, the blood slowly diffuses from the central to the peripheral sinusoids, and the blood gas levels are similar to those of venous blood. During erection, the rapid entry of arterial blood to both the central and the peripheral sinusoids changes the intracavernous blood gas levels to those of arterial blood (Sattar et al, 1995).

The structure of the corpus spongiosum and glans is similar to that of the corpora cavernosa except that the sinusoids are larger. The tunica is thinner in the spongiosum (with only a circular layer [see earlier]) and is absent in the glans (Table 26-2).

Arteries

The source of penile blood is usually the internal pudendal artery, a branch of the internal iliac artery (Fig. 26-3A). In many instances, however, accessory arteries exist, arising from the external iliac, obturator, and vesical and femoral arteries, and they may constitute the dominant or only arterial supply to the corpus cavernosum in some men (Breza et al, 1989). In a study of 20 fresh human cadavers, Droupy and colleagues (1997) reported three patterns of penile arterial supply: type I, arising exclusively from internal pudendal arteries (in 3 of 20 samples); type II, arising from both accessory and internal pudendal arteries

(in 14 of 20 samples); and type III, arising exclusively from accessory pudendal arteries (in 3 of 20 samples). Nehra and colleagues (2008) studied 79 consecutive patients with a history of ED and noted that 35% had an accessory pudendal artery, typically arising from the obturator artery. In these men, the accessory pudendal was the dominant blood supply in 54% and the only corporeal blood supply in 11%. The importance of accessory pudendal artery preservation during radical prostatectomy was demonstrated by Mulhall and colleagues (2008), who reported more rapid recovery of sexual function in men who underwent artery-sparing radical prostatectomy.

The internal pudendal artery becomes the common penile artery after giving off a branch to the perineum. The three branches of the penile artery are the dorsal, bulbourethral, and cavernous. Distally, they join to form a vascular ring near the

TABLE 26-2 Penile Components and Their Function during Penile Erection

COMPONENT	FUNCTION
Corpora cavernosa	Support corpus spongiosum and glans
Tunica albuginea (of corpora cavernosa)	Contains and protects erectile tissue Provides rigidity of the corpora cavernosa Participates in veno-occlusive mechanism
Smooth muscle	Regulates blood flow into and out of the sinusoids
Ischiocavernosus muscle	Pumps blood distally to hasten erection Provides additional penile rigidity during rigid erection phase
Bulbocavernosus muscle	Compresses the bulb to help expel semen
Corpus spongiosum	Pressurizes and constricts the urethral lumen to allow forceful expulsion of semen
Glans	Acts as a cushion to lessen the impact of penis on female organs Provides sensory input to facilitate erection and enhance pleasure Facilitates intromission because of its cone shape

Figure 26-3. A, Penile arterial supply. B, Scanning electron micrograph of a human penile cast showing helicine arteries opening directly into the sinusoids without intervening capillaries.

glans. The dorsal artery is responsible for engorgement of the glans during erection. The bulbourethral artery supplies the bulb and corpus spongiosum. The cavernous artery effects tumescence of the corpus cavernosum and enters it at the hilum of the penis, where the two crura merge. It gives off many helicine arteries along its course, which supply the trabecular erectile tissue and the sinusoids (Fig. 26-3B). These helicine arteries are contracted and tortuous in the flaccid state and become dilated and straight during erection. Diallo and associates (2013) noted that in four of their five cadaveric specimens, the dorsal artery sent two to four penetrating branches to join the cavernous artery and supply blood to the distal one third of the penis. The bulbourethral and urethral arteries are situated outside the tunica albuginea of the corpus spongiosum on the lateral and dorsal sides. Anastomosis of the cavernous and urethral arteries occurs outside the tunica of the spongiosum.

Veins

The venous drainage from the three corpora originates in tiny venules leading from the peripheral sinusoids immediately beneath the tunica albuginea. These venules travel in the trabeculae between the tunica and the peripheral sinusoids to form the subtunical venous plexus before exiting as the emissary veins (Fig. 26-4A). Outside the tunica albuginea, venous drainage is as follows.

Skin and Subcutaneous Tissue. Multiple superficial veins run subcutaneously and unite near the root of the penis to form a single (or paired) superficial dorsal vein, which drains into the saphenous veins. Occasionally, the superficial dorsal vein may also drain a portion of the corpora cavernosa.

Pendulous Penis. The emissary veins from the corpus cavernosum and spongiosum drain dorsally to the deep dorsal, laterally to the

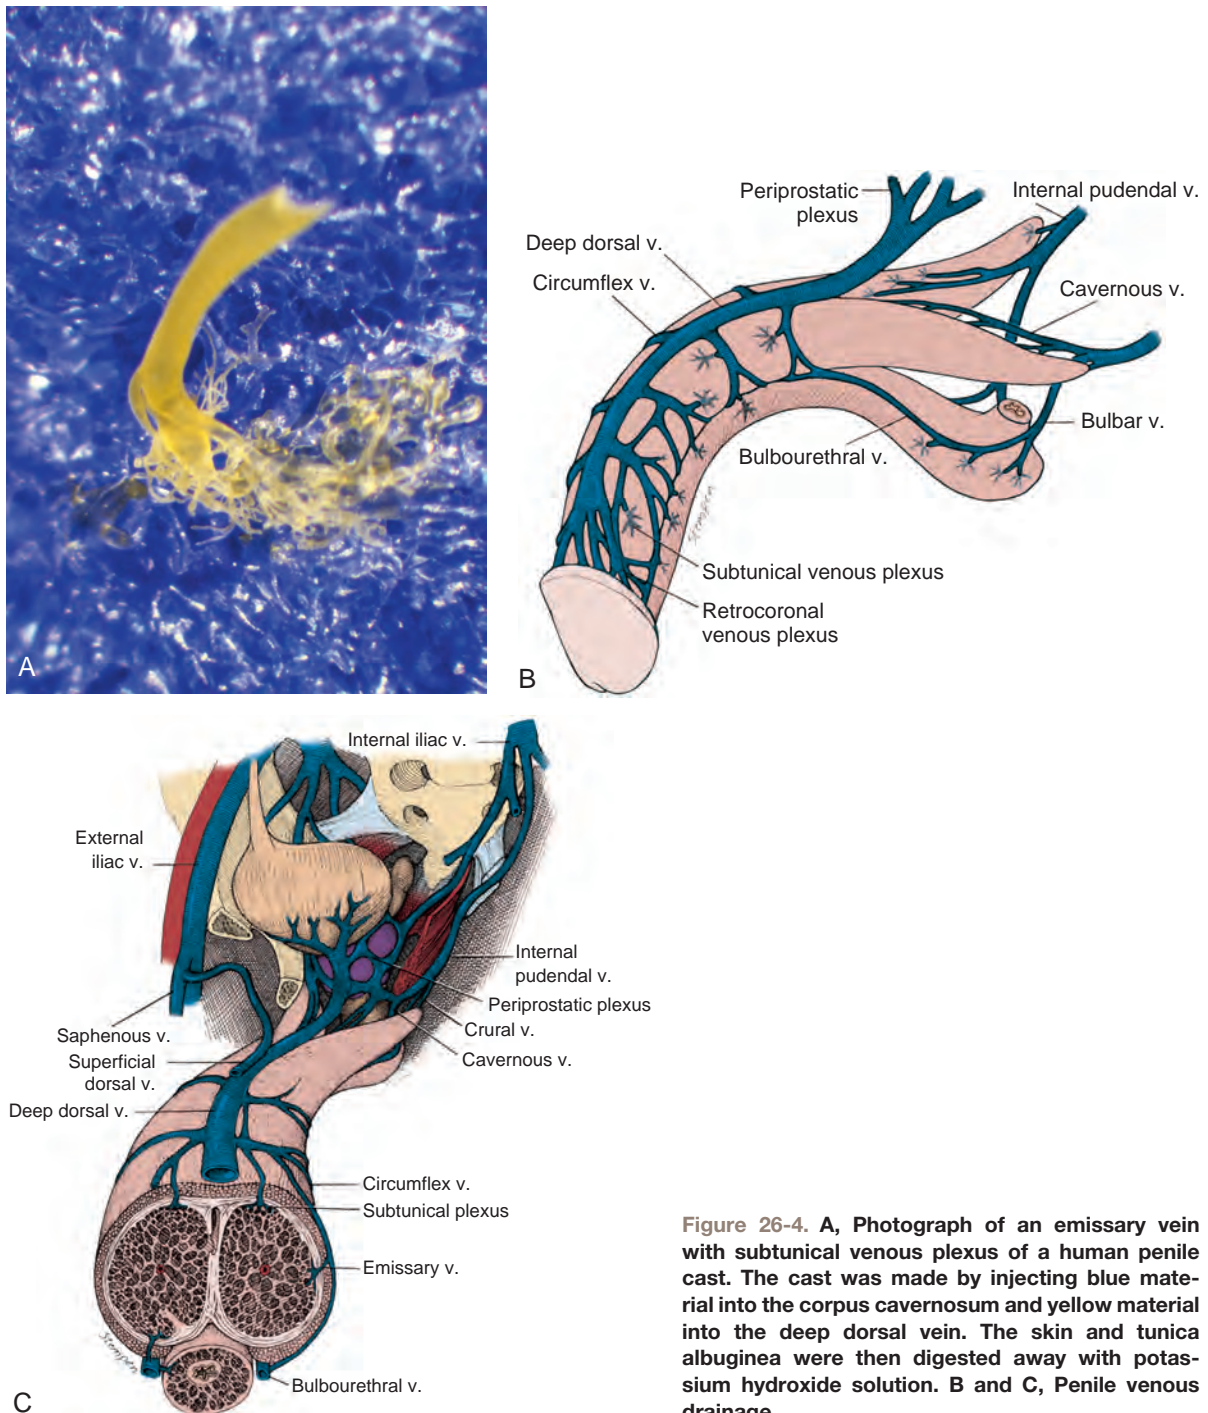

Figure 26-4. A, Photograph of an emissary vein with subtunical venous plexus of a human penile cast. The cast was made by injecting blue material into the corpus cavernosum and yellow material into the deep dorsal vein. The skin and tunica albuginea were then digested away with potassium hydroxide solution. B and C, Penile venous drainage.

circumflex, and ventrally to the periurethral veins. Beginning at the coronal sulcus, multiple venous channels coalesce to form the deep dorsal vein, which is the main venous drainage of the glans penis and distal two thirds of the corpora cavernosa. Usually a single vein, but sometimes more than one deep dorsal vein, runs upward behind the symphysis pubis to join the periprostatic venous plexus. There are also small venous channels accompanying the paired dorsal artery. Periarterial veins also travel longitudinally to join the dorsal vein or Santorini plexus proximally (Hsu et al, 2003). These become enlarged after the deep dorsal vein is ligated and may be the cause of recurrent leakage in venogenic ED (Chen et al, 2005). **Infrapubic Penis.** Emissary veins draining the proximal corpora cavernosa join to form cavernous and crural veins. These join the periurethral veins from the urethral bulb to form the internal pudendal veins.

The veins of the three systems communicate variably with each other. Variations in the number, distribution, and termination of these venous systems are common (Fig. 26-4B and C). In fresh cadavers, Hsu and coworkers (2012) determined the following percentage of venous flow from the corpora: deep dorsal vein, 65%; cavernous vein, 11.9%; periarterial vein, 11.4%; others, 15.6%. The study was performed in cadavers, and the cavernous vein is not the same as described by others.

Hemodynamics and Mechanism of Erection and Detumescence

Corpora Cavernosa

The penile erectile tissue, specifically the cavernous smooth musculature and the smooth muscles of the arteriolar and arterial walls, plays a key role in the erectile process. In the flaccid state,

these smooth muscles are tonically contracted, allowing only a small amount of arterial flow into the corpora. The blood partial pressure of oxygen (PO_2) is about 35 mm Hg (Sattar et al, 1995). The flaccid penis is in a moderate state of contraction, as evidenced by further shrinkage in cold weather and after phenylephrine injection.

Sexual stimulation triggers release of neurotransmitters from the cavernous nerve terminals. This release of neurotransmitters results in relaxation of these smooth muscles and the following events (Fig. 26-5): (1) dilation of the arterioles and arteries by increased blood flow in the diastolic and systolic phases; (2) trapping of the incoming blood by the expanding sinusoids; (3) compression of the subtunical venous plexuses between the tunica albuginea and the peripheral sinusoids, reducing venous outflow; (4) stretching of the tunica to its capacity, which occludes the emissary veins between the inner circular and outer longitudinal layers and further decreases venous outflow; and (5) increase in PO_2 (to about 90 mm Hg) and intracavernous pressure (around 100 mm Hg), which raises the penis from the dependent position to the erect state (the full-erection phase). A further pressure increase (to several hundred millimeters of mercury) can occur with reflex contractions of the ischiocavernosus muscles (rigid-erection phase) during sexual stimulation.

The angle of the erect penis is determined by its size and attachment to the puboischial rami (the crura) and the anterior surface of the pubic bone (the suspensory and funiform ligaments). In men with a long heavy penis or a loose suspensory ligament, the penis usually points downward, even with full rigidity.

Three phases of detumescence were reported in an animal study (Bosch et al, 1991). The first entails a transient intracorporeal pressure increase, indicating the beginning of smooth muscle

Figure 26-5. The mechanism of penile erection. A, In the flaccid state, the arteries, arterioles, and sinusoids are contracted. The intersinusoidal and subtunical venous plexuses are wide open, with free flow to the emissary veins. B, In the erect state, the muscles of the sinusoidal wall and the arterioles relax, allowing maximal flow to the compliant sinusoidal spaces. Most of the venules are compressed between the expanding sinusoids. The larger venules are sandwiched and flattened between the distended sinusoids and the tunica albuginea. This effectively reduces the venous capacity to a minimum. C and D, Scanning electron micrographs of casts of a canine subtunical venous plexus in the flaccid (C) and erect (D) states. (A and B, From Lue TF, Giuliano F, Khoury S, et al. Clinical manual of sexual medicine: sexual dysfunction in men. Paris: Health Publications; 2004.)

contraction against a closed venous system. The second phase shows a slow pressure decrease, suggesting a slow reopening of the venous channels with resumption of the basal level of arterial flow. The third phase shows a fast pressure decrease with fully restored venous outflow capacity.

Erection involves sinusoidal relaxation, arterial dilation, and venous compression (Lue et al, 1983). The importance of smooth muscle relaxation has been demonstrated in animal and human studies (Saenz de Tejada et al, 1989a; Ignarro et al, 1990). To summarize the hemodynamic events of erection and detumescence, seven phases have been observed in animal experiments that reflect the changes in and the relationship between penile arterial flow and intracavernous pressure (Fig. 26-6).

Corpus Spongiosum and Glans Penis

The hemodynamics of the corpus spongiosum and glans penis differ from those of the corpora cavernosa. During erection, the arterial flow increases in a similar manner; however, the pressure in the corpus spongiosum and glans is only one third to one half that in the corpora cavernosa because the tunical covering, which is thin over the corpus spongiosum and virtually absent over the glans, ensures minimal venous occlusion. During the full-erection phase, partial compression of the deep dorsal and circumflex veins between Buck fascia and the engorged corpora cavernosa contributes to glanular tumescence, although the spongiosum and glans essentially function as a large arteriovenous shunt during this phase. In the rigid-erection phase, the ischiocavernosus and bulbocavernosus muscles forcefully compress the spongiosum and penile veins, resulting in further engorgement and increased pressure in the glans and spongiosum (Table 26-3).

Neuroanatomy and Neurophysiology of Penile Erection

Spinal Centers and Peripheral Pathways

The innervation of the penis is both autonomic (sympathetic and parasympathetic) and somatic (sensory and motor) (Fig. 26-7). From the neurons in the spinal cord and peripheral ganglia, the sympathetic and parasympathetic nerves merge to form the cavernous nerves, which enter the corpora cavernosa and corpus spongiosum to modulate the neurovascular events during erection and detumescence. The somatic nerves are primarily responsible for

sensation and the contraction of the bulbocavernosus and ischiocavernosus muscles.

Autonomic Pathways. The sympathetic pathway originates from the 11th thoracic to the 2nd lumbar spinal segments and passes through the white rami to the sympathetic chain ganglia. Some fibers travel through the lumbar splanchnic nerves to the inferior mesenteric and superior hypogastric plexuses, from which fibers travel in the hypogastric nerves to the pelvic plexus. In humans, the T10 to T12 segments are most often the origin of the sympathetic fibers, and the chain ganglia cells projecting to the penis are located in the sacral and caudal ganglia (de Groat and Booth, 1993).

The parasympathetic pathway arises from neurons in the intermediolateral cell columns of the second, third, and fourth sacral spinal cord segments. The preganglionic fibers pass in the pelvic nerves to the pelvic plexus, where they are joined by the sympathetic nerves from the superior hypogastric plexus. The cavernous nerves are branches of the pelvic plexus that innervate the penis. Other branches innervate the rectum, bladder, prostate, and sphincters. The cavernous nerves are easily damaged during radical excision of the rectum, bladder, and prostate. A clear understanding of the course of these nerves is essential to the prevention of iatrogenic ED (Walsh et al, 1990). Human cadaveric dissection has revealed medial and lateral branches of the cavernous nerves (the former accompanying the urethra and the latter piercing the urogenital diaphragm 4 to 7 mm lateral to the sphincter) and multiple communications between the cavernous and dorsal nerves (Paick et al, 1993) (Fig. 26-8). In addition to the cavernous nerve proper, pelvic ganglion cells exist in and along the nerve components and pelvic viscera. These are seen at the bladder/prostate junction, the dorsal aspect of the seminal vesicles, and along the prostate. Takenaka and colleagues (2005) reported

TABLE 26-3 Comparison of Corpus Spongiosum and Glans Penis

	CORPUS SPONGIOSUM	GLANS PENIS
Tunica albuginea	Thin (circular layer only)	Absent
Main blood supply	Bulbal and spongiosal arteries	Dorsal artery
Venous occlusion during erection	No	No
Compression by skeletal muscle	Yes (ischiocavernosus, bulbocavernosus)	No

Figure 26-6. Blood flow and intracavernous pressure changes during the seven phases of penile erection and detumescence: 0, flaccid; 1, latent; 2, tumescence; 3, full erection; 4, rigid erection; 5, initial detumescence; 6, slow detumescence; 7, fast detumescence.

individual variations in distribution of these extramural ganglion cells in the male pelvis, which may complicate nerve-sparing efforts.

Stimulation of the pelvic plexus and the cavernous nerves induces erection, whereas stimulation of the sympathetic trunk causes detumescence. This clearly implies that the sacral parasympathetic input is responsible for tumescence, and the thoracolumbar sympathetic pathway is responsible for detumescence. In experiments with cats and rats, removal of the spinal cord below L4 or L5 reportedly eliminated the reflex erectile response, but placement with a female in heat or electrical stimulation of the medial preoptic area (MPOA) produced marked erection (Giuliano et al, 1996; Sato and Christ, 2000). Paick and Lee (1994) also reported that apomorphine-induced erection is similar to psychogenic erection in the rat and can be induced via the thoracolumbar sympathetic pathway in case of injury to the sacral parasympathetic centers. Many men with sacral spinal cord injury retain psychogenic erectile ability even though reflexogenic erection is abolished. These cerebrally elicited erections are found more frequently in patients with lower motoneuron lesions below T12 (Courtois et al, 1999); no psychogenic erection occurs in patients with lesions above T9. The efferent sympathetic outflow is suggested to be at the levels T11 and T12 (Chapelle et al, 1980). These authors also reported that in patients with psychogenic erections, lengthening and swelling of the penis are observed, but rigidity is insufficient.

It is possible that for production of rigid erection in normal men, cerebral impulses travel as follows: inhibiting the sympathetic pathway and decreasing norepinephrine release; through the parasympathetic pathway, releasing NO and acetylcholine; and through the somatic pathway, releasing acetylcholine. In patients with a sacral cord lesion, the cerebral impulses can still travel via the sympathetic pathway to inhibit norepinephrine release, and NO and acetylcholine can still be released through synapse with

postganglionic parasympathetic and somatic neurons. Because the number of these synapses is less than in men with an intact sacral spinal cord, the resulting erection will not be as strong.

Somatic Pathways. The somatosensory pathway originates at the sensory receptors in the penile skin, glans, and urethra and within the corpus cavernosum. There are numerous afferent terminations in the human glans penis: free nerve endings and corpuscular receptors in a ratio of 10:1. The free nerve endings are derived from thin myelinated A_δ and unmyelinated C fibers and are unlike any other cutaneous area in the body (Halata and Munger, 1986). The nerve fibers from the receptors converge to form bundles of the dorsal nerve of the penis, which joins other nerves to become the pudendal nerve. The latter enters the spinal cord via the S2–S4 roots to terminate on spinal neurons and interneurons in the central gray region of the lumbosacral segment (McKenna, 1998). Activation of these sensory neurons sends messages of pain, temperature, and touch by means of spinothalamic and spinoreticular pathways to the thalamus and sensory cortex for sensory perception.

Kozacioglu and associates (2014) reported a detailed study of the dorsal nerve. They noted that the dorsal nerve of the penis is composed of two to six branches, and in 16 of 22 adult cadaveric specimens, branches perforating the tunica albuginea to the corpus cavernosum were noted. The dorsal nerve of the penis previously was regarded as purely somatic; however, nerve bundles testing positive for NOS, which is autonomic in origin, have been demonstrated in humans by Burnett and colleagues (1993) and in rats by Carrier and colleagues (1995). These NOS-positive nerve bundles in the dorsal nerve are reduced after damage of the cavernous nerve near the rat prostate. Giuliano and coworkers (1993) have also shown that stimulation of the sympathetic chain at the L4–L5 level elicits an evoked discharge on the dorsal nerve and that stimulation of the dorsal nerve evokes a reflex discharge in the lumbosacral sympathetic chain of rats. These findings demonstrate that the dorsal nerve has somatic and autonomic components that enable it to regulate erectile and ejaculatory functions.

The Onuf nucleus in the second to fourth sacral spinal segments is the center of somatomotor penile innervation. These nerves travel in the sacral nerves to the pudendal nerve to innervate the ischiocavernosus and bulbocavernosus muscles. Contraction of the ischiocavernosus muscles produces the rigid-erection phase. Rhythmic contraction and compression of the bulbocavernosus muscle on the proximal corpus spongiosum helps semen expulsion, provided that the external sphincter is relaxed and the urethral lumen is compressed by the engorged spongiosum. In animal studies, direct innervation of the sacral spinal motoneurons by brainstem sympathetic centers (A5-catecholaminergic cell group and locus ceruleus) has been identified (Marson and McKenna, 1996). This adrenergic innervation of pudendal motoneurons may be involved in rhythmic contractions of perineal muscles during ejaculation. Oxytocinergic and serotonergic innervation of lumbosacral nuclei controlling penile erection and perineal muscles in male rats has also been demonstrated (Tang et al, 1998).

Depending on the intensity and nature of genital stimulation, several spinal reflexes can be elicited (Table 26-4). The best known is the bulbocavernosus reflex, which is the basis of genital neurologic examination and electrophysiologic latency testing. Although impairment of bulbocavernosus and ischiocavernosus muscles may impair erection, the significance of obtaining a bulbocavernosus reflex in overall sexual dysfunction assessment is controversial.

Supraspinal Pathways and Centers

Integration and processing of afferent inputs (e.g., visual, olfactory, imaginative, genital stimulation) in the supraspinal centers are essential in the initiation and maintenance of penile erection. A spinal transection study at the T8 level by Hubscher and associates (2010) revealed that ascending bilateral projections in the dorsal, dorsolateral, and ventrolateral white matter of the spinal cord convey information from the male external genitalia to the medullary reticular formation. The authors postulate that these multiple spinal pathways may correspond to different functions, including

TABLE 26-4 Spinal Reflexes Involved in Stimulation of Penile Dorsal Nerve

STIMULATION	SPINAL CENTER	EFFERENT	EFFECT
Noxious, abrupt stimulation	Sacral motor neurons	Pudendal nerve (motor)	Bulbocavernosus reflex
Low-intensity continuous (e.g., vibratory, manual)	Sacral parasympathetic neurons and interneurons	1. Pelvic nerves 2. Cavernous nerve	1. Bladder inhibition and closure of bladder neck 2. Penile erection
High-intensity continuous	Sacral motor and parasympathetic Thoracolumbar sympathetic neurons	Pudendal, pelvic, and cavernous nerves	Ejaculation

TABLE 26-5 Brain Centers Involved in Sexual Function

LEVEL	REGION	FUNCTION
Forebrain	Medial amygdala	Control sexual motivation
	Stria terminalis	
	Pyriform cortex	Inhibits sexual drive (hypersexuality when destroyed)
	Hippocampus	Involved in penile erection
	Right insula and inferior frontal cortex Left anterior cingulate cortex	Increased activity during visually evoked sexual stimulation (sexual arousal)
Hypothalamus	Medial preoptic area	Ability to recognize a sexual partner, integration of hormonal and sensory cues
	Lateral preoptic area	Control nocturnal penile tumescence in rats
	Paraventricular nucleus	Facilitates penile erection (via oxytocin neurons to lumbosacral spinal autonomic and somatic efferents)
Brainstem	Nucleus paragigantocellularis	Inhibits penile erection (via serotonin neurons to lumbosacral spinal neurons and interneurons)
	A5-catecholaminergic cell group	Major noradrenergic center
	Locus ceruleus	
Midbrain	Periaqueductal gray	Relay center for sexually relevant stimuli

functions processing affective, pleasure, and motivational; nociception; and mating-specific (e.g., for erection and ejaculation) inputs. In animal studies, the central supraspinal systems controlling sexual arousal are localized predominantly in the limbic system (e.g., olfactory nuclei, MPOA, nucleus accumbens, amygdala, and hippocampus) and hypothalamus (paraventricular and ventromedial nuclei). In particular, the medial amygdala, MPOA, paraventricular nucleus (PVN), periaqueductal gray, and ventral tegmentum are recognized as key structures in the central control of the male sexual response (Andersson, 2011; Melis and Argiolas, 2011).

In humans, positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) have allowed a greater understanding of brain activation during human sexual arousal by demonstrating increases in regional cerebral blood flow or changes in regional cerebral activity during a particular moment in time. Generally, in young heterosexual men, sexual arousal is triggered with sexually explicit pictures or videos. Scanned brain images taken during arousal are compared with images taken in response to sexually neutral media (e.g., documentaries or humorous video clips). Centers of activation and deactivation can be demonstrated. Although the simplicity of these study designs is elegant, multiple factors are involved in sexual arousal—especially when triggered by visual clues. The authors of these studies have placed many necessary conditions in experiments in an attempt to standardize the methods and participants; however, the complexity of human emotion and sexual response is extremely difficult to regulate (Table 26-5).

Kühn and Gallinat (2011) performed a quantitative meta-analysis of 11 fMRI studies that compared brain activity in response to erotic visual stimuli versus neutral visual stimuli. The meta-analysis identified a neural network that constitutes a core circuit of male sexual

arousal in humans and consists of the following components: cognitive (parietal cortex, anterior cingulate gyrus, thalamus, insula), emotional (amygdala, insula), motivational (precentral gyrus, parietal cortex), and physiologic (hypothalamus/thalamus, insula).

Using fMRI, detailed comparisons of brain activation in response to visual sexual stimuli have also been performed on varied groups. Stoléru and colleagues (2003) compared healthy men with men with hypoactive sexual desire disorder and reported that the left gyrus rectus, a portion of the medial orbitofrontal cortex, remained activated in the latter group in contrast to its deactivation in healthy men. This region is believed to mediate inhibition of motivated behavior, and its continued activation may help explain the pathophysiology of hypoactive sexual desire disorder. Montorsi and colleagues (2003) compared men with psychogenic ED and potent control subjects after the administration of apomorphine. During visual sexual stimulation, the men with psychogenic ED evidenced extended activation of the cingulate gyrus, frontal mesial, and frontal basal cortex, suggesting an underlying organic cause for psychogenic ED. However, fMRI images obtained after apomorphine were similar to the images of the potent control subjects. Apomorphine caused additional activation of foci in the patients with psychogenic ED (seen in the nucleus accumbens, hypothalamus, and mesencephalon), and it was significantly greater in the right hemisphere than in the left. This greater right-sided activation is a common finding in sexually evoked brain activation studies.

Brain scanning with PET and fMRI has become a powerful tool in the study of central activation of sexual arousal, with many brain regions of activation demonstrated in these studies (Table 26-6). Psychogenic ED, premature ejaculation, sexual deviations, and orgasmic dysfunction are just a few conditions that may accompany alterations in higher brain function and perhaps now can be

studied. As we begin to understand brain function with normal sexual response and arousal, the causes of dysfunction may be elucidated.

The structures discussed earlier are responsible for the three types of erection: psychogenic, reflexogenic, and nocturnal. **Psychogenic erection is a result of audiovisual stimuli or fantasy. Impulses from the brain modulate the spinal erection centers (T11-L2 and S2-S4) to activate the erectile process.** Reflexogenic erection is produced by tactile stimulation of the genital organs. The impulses reach the spinal erection centers; some then follow the ascending tract, resulting in sensory perception, whereas others activate the autonomic nuclei to send messages via the cavernous nerves to the penis to induce erection. This type of erection is preserved in patients with upper spinal cord injury. Nocturnal erection occurs mostly during rapid eye movement (REM) sleep. PET scanning of humans in REM sleep shows increased activity in the pontine area, the amygdalae, and the anterior cingulate gyrus but decreased activity in the prefrontal and parietal cortex. The mechanism that triggers REM sleep is located in the pontine reticular formation; the cholinergic neurons in the lateral pontine tegmentum are activated, whereas the adrenergic neurons in the locus ceruleus and the serotonergic neurons in the midbrain raphe are silent. In a brain stimulation study in rats, the sites for eliciting erection during REM sleep were located in the dorsal and intermediate parts of the lateral septum, whereas the ventral part of the lateral septum was the most effective site for eliciting erections during wakefulness (Gulia et al, 2008).

The brain centers activated during orgasm and ejaculation have also been studied. Holstege and colleagues (2003) used PET to

measure increases in regional cerebral blood flow during ejaculation versus sexual stimulation without orgasm in heterosexual volunteers. Manual penile stimulation was performed by the volunteer's female partner. Primary brain activation was found in the mesodiencephalic transition zone (including the ventral tegmental area), an area frequently activated with "reward" behaviors and with injection of opioids such as heroin. Other activated mesodiencephalic structures included the midbrain lateral central tegmental field; the zona incerta; the subparafascicular nucleus; and the ventroposterior, midline, and intralaminar thalamic nuclei. Increased activation was also observed in the lateral putamen and adjoining parts of the claustrum. Neocortical activity was found in Brodmann areas 7/40, 18, 21, 23, and 47, exclusively on the right side. Conversely, in the amygdala and adjacent entorhinal cortex, a decrease in activation was observed. Remarkably strong increases in blood flow were observed in the cerebellum. These findings corroborate the notion that the cerebellum plays an important role in emotional processing. Although activation of these particular areas is of great interest, further studies are necessary to understand completely the neurobiology of orgasm, ejaculation, and sexual satisfaction in men (Table 26-7).

Neurotransmitters

Peripheral Neurotransmitters and Endothelium-Derived Factors

Flaccidity and Detumescence. α -Adrenergic nerve fibers and receptors have been demonstrated in the cavernous trabeculae and surrounding the cavernous arteries, and norepinephrine has generally been accepted as the principal neurotransmitter to keep the penis in the flaccid state (Andersson, 2011; Dieckerichs et al, 1990). Both α_1 -adrenergic and α_2 -adrenergic receptors have been demonstrated in human corpus cavernosum tissue (Prieto, 2008). Research findings support a functional predominance of postjunctional α_1 -adrenergic receptors for contraction and of prejunctional α_2 -adrenergic receptors for downregulating not only release of norepinephrine but also NO (Prieto, 2008). Norepinephrine, released from adrenergic nerves, stimulates adrenergic receptors in the penile vessels and corpus cavernosum, producing a contraction that involves Ca^{2+} entry through calcium channels as well as calcium sensitization mechanisms mediated by protein kinase C, tyrosine kinases, and Rho-kinase (Andersson, 2011).

Endothelin-1, synthesized by endothelium, is a more potent vasoconstrictor than epinephrine and has been suggested to be a mediator for detumescence (Holmquist et al, 1990; Saenz de Tejada et al, 1991a). Endothelin-1 induces slowly developing, long-lasting contractions in different smooth muscles of the penis: corpus cavernosum, cavernosal artery, deep dorsal vein, and penile circumflex veins. Endothelin also potentiates the constrictor effects of catecholamines on trabecular smooth muscle (Christ et al, 1995b). Two receptors for endothelin, endothelin-A and endothelin-B, mediate the biologic effects of endothelin in vascular tissue: Endothelin-A receptors mediate contraction, whereas endothelin-B receptors induce relaxation.

TABLE 26-6 Common Brain Activation Regions with Visual Sexual Stimuli*

BRAIN ACTIVATION REGIONS	FUNCTIONAL ASSOCIATION
Bilateral inferior temporal cortex (right > left)	Visual association area
Right insula	Processes somatosensory information with motivational states
Right inferior frontal cortex	Processes sensory information
Left anterior cingulate cortex	Controls autonomic and neuroendocrine function
Right occipital gyrus	Visual processing
Right hypothalamus	Male copulatory behavior
Left caudate (the striatum)	Processes attention and guides responsiveness to new environmental stimuli

*These regions demonstrate activation with visual sexual stimuli in multiple studies.

TABLE 26-7 Brain Centers of Orgasm

	BRAIN AREAS	RELEVANCE
Increased activity: primary area	Mesodiencephalic transition zone (including the ventral tegmental area)	"Reward" center also activated by opioid
Increased activity: secondary areas	Midbrain lateral central tegmental field, the zona incerta, subparafascicular nucleus, ventroposterior, midline, and intralaminar thalamic nuclei Lateral putamen and adjoining parts of the claustrum Brodmann areas 7/40, 18, 21, 23, and 47, exclusively on the right side	
Increased activity: other area	Cerebellum	Emotional processing
Decreased activity	Amygdala and adjacent entorhinal cortex	

Several constrictor prostanoids, including prostaglandin I_2 (PGI_2), prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$), and thromboxane A_2 (TXA_2), are synthesized by the human cavernous tissue. In vitro studies demonstrated that prostanoids are responsible for the tone and spontaneous activity of isolated trabecular muscle (Christ et al, 1990). Functional characterization of prostanoid receptors in human trabecular and arterial penile smooth muscle revealed that only thromboxane A_2 (TP) receptors mediate contractile effects of prostanoids in these tissues (Angulo et al, 2002). Also, it has been observed in vitro that constrictor prostanoids, simultaneously released with NO, attenuate the dilator effect of NO (Azadzoi et al, 1992; Minhas et al, 2001).

The renin-angiotensin system (RAS) may also play a significant role in the maintenance of penile smooth muscle tone. The RAS comprises two major arms: a vasoconstrictor/proliferative arm, in which the main mediator is angiotensin II acting on angiotensin (AT1) receptors, and a vasodilator/antiproliferative arm in which the major effector is angiotensin-(1-7) acting via the G protein-coupled receptor Mas (Sousa et al, 2010). The mediators and receptors of both arms have been demonstrated in the corpus cavernosum. The RAS system may have a dual role in erectile function: pro-detumescence mediated by the angiotensin II-AT1 axis and pro-erection mediated by the angiotensin-(1-7)-Mas axis. Uckert and associates (2012) have also reported a decrease in cavernous blood level of neuropeptide Y during sexual arousal and suggested that neuropeptide Y may contribute to maintenance of a flaccid penis. In addition, the endothelium has been shown to release potent vasoconstrictors, including endoperoxides, TXA_2 , and superoxide anions.

The current consensus holds that the maintenance of the intracorporeal smooth muscle in a semicontracted (flaccid) state likely results from three factors: intrinsic myogenic activity (Andersson and Wagner, 1995); adrenergic neurotransmission; and endothelium-derived contracting factors such as angiotensin II, $PGF_{2\alpha}$, and endothelin-1. Detumescence after erection may be a result of cessation of NO release, the breakdown of cyclic guanosine monophosphate (cGMP) by PDEs, and/or sympathetic discharge during ejaculation.

Erection. Acetylcholine has been shown to be released with electrical field stimulation of human erectile tissue (Blanco et al, 1988). Traish and colleagues (1990) reported the density of muscarinic receptors in cavernous tissue to range from 35 to 65 fmol/mg protein and in endothelial cell membrane from 5 to 10 fmol/mg protein. However, intravenous or intracavernous injection of atropine failed to abolish erection induced in animals by electrical neurostimulation (Stief et al, 1989a) and in men by erotic stimuli (Wagner and Uhlenhuth, 1980). Although acetylcholine is not the predominant neurotransmitter, it contributes indirectly to penile erection by presynaptic inhibition of adrenergic neurons and stimulation of NO release from endothelial cells (Saenz de Tejada et al, 1989a).

Most researchers now agree that NO released from nonadrenergic/noncholinergic neurotransmission and from the endothelium is the principal neurotransmitter mediating penile erection. NO increases the production of cGMP, which relaxes the cavernous smooth muscle (Ignarro et al, 1990; Kim et al, 1991; Burnett et al, 1992; Rajfer et al, 1992; Trigo-Rocha et al, 1993; Andersson, 2011). The consensus is that NO derived from neuronal nitric oxide synthase (nNOS) in the nitrergic nerves is responsible for the initiation, whereby NO from endothelial nitric oxide synthase (eNOS) contributes to the maintenance of smooth muscle relaxation and erection (Hurt et al, 2002). (For a more detailed discussion of NO, see specific Nitric Oxide sections.)

Aside from its role in releasing vasoconstrictors, the endothelium can also release factors that induce smooth muscle relaxation, including carbon monoxide (CO), endothelium-derived hyperpolarizing factor (EDHF), prostacyclin (PGI_2), and endothelin (which may induce relaxation via activation of endothelin-B receptors).

Interactions among Nerves and Neurotransmitters. Acetylcholine, by acting on the presynaptic receptors on adrenergic neurons,

has been shown to modulate the release of norepinephrine (Saenz de Tejada et al, 1989b), which also can be inhibited by PGE_1 (Moldenings et al, 1992). In the human corpus cavernosum, noradrenergic responses are under nitrergic control. Conversely, adrenergic neurons, through prejunctional α_2 receptors, can also regulate the release of NO.

Several studies have demonstrated that the interaction between the two systems also occurs in the smooth muscle (Brave et al, 1993; Angulo et al, 2001a). The NO-cGMP-protein kinase G (PKG)-I pathway can lead to inhibition at several sites on the noradrenergic contractile pathway in the vascular smooth muscle, impairing inositol 1,4,5-triphosphate (IP3) production by phospholipase C (Hirata et al, 1990), IP3 receptor activity (Schlossmann et al, 2000), and the RhoA/Rho-kinase pathway (Sauzeau et al, 2000). However, interaction sites have not yet been identified in penile smooth muscle. A nitrergic-noradrenergic imbalance owing to defective nitrergic neurotransmission has been implicated in penile tissue from patients and in animal models with ED (Christ et al, 1995a; Celtek et al, 1999). Similar to the interaction between nitrergic and noradrenergic pathways, vasoconstrictive actions of endothelin have been shown to be inhibited by NO during erection (Mills et al, 2001).

Numerous factors have been reported to increase NOS activity and NO release, including molecular oxygen, androgen, long-term administration of L-arginine, and repeated intracavernous injection of PGE_1 (Kim et al, 1993; Escrig et al, 1999; Marin et al, 1999). Decreased NOS activity has been associated with castration, denervation, hypercholesterolemia, and diabetes mellitus. Interaction of different types of NOS may also occur. For example, nNOS activity has been shown to decrease and inducible nitric oxide synthase (iNOS) levels to increase after injection of transforming growth factor (TGF)- β 1 into the penis (Bivalacqua et al, 2000), and eNOS levels are reportedly significantly higher in nNOS-knockout mice (Burnett et al, 1996).

In a study of neurotransmitters in human corpus cavernosum and spongiosum, Hedlund and colleagues (2000b) reported that vesicular acetylcholine transporter, vasoactive intestinal polypeptide (VIP), and nNOS are found in the same nerve terminals. Tyrosine hydroxylase-positive nerves do not contain vesicular acetylcholine transporter, VIP, or NOS. Heme oxygenase (HO) enzymes HO-1 and HO-2 and eNOS are localized to the endothelium. Interaction of these neurotransmitters may modify the effect of parasympathetic and sympathetic activation on penile function.

Role of Caveolae. Caveolae are invaginated microdomains of plasma membrane that are rich in eNOS and caveolins as well as cholesterol, sphingolipids, and glycosylphosphatidylinositol-linked proteins. In addition, caveolae contain numerous other signaling proteins, such as receptors with seven-transmembrane domains, G proteins, adenylyl cyclase, phospholipase C, protein kinase C, calcium pumps, and calcium channels. Decreased caveolin-1 expression has been reported in the cavernous smooth muscle of aged rats (Bakircioglu et al, 2001). Linder and colleagues (2006) demonstrated that penile erection requires association of soluble guanylyl cyclase with endothelial caveolin-1 in rat corpus cavernosum. Shakhrova and colleagues (2009) reported that nerve-mediated relaxation of penile tissue from caveolin-1-deficient mice was impaired. Caveolin-1 in both the cavernous smooth muscle and the endothelium is decreased after bilateral cavernous nerve injury (Becher et al, 2009). In a rat model with diabetes induced by fructose and streptozotocin, Elcioglu and associates (2010) reported attenuation of erectile responses in both diabetic groups, an enhanced expression of caveolin-1, and a decrease in the eNOS activity with a concomitant decrease in NO synthesis. These reports strongly suggest that the caveolae and caveolin are involved in the regulation of penile function.

Central Neurotransmitters and Neuropeptides. Numerous neurotransmitters and neuropeptides have been implicated in regulation of sexual function. The major ones are dopamine, oxytocin, NO, norepinephrine, serotonin (5-hydroxytryptamine [5-HT]), and prolactin. In general, dopaminergic and adrenergic

receptors promote sexual function, and 5-HT receptors inhibit it (Foreman and Wernicke, 1990). Androgens also have an important role in modulating the effect of the transmitters.

Dopamine. There are many dopaminergic systems in the brain with ultrashort, intermediate, and long axons. The cell bodies are located in the ventral tegmentum, substantia nigra, and hypothalamus. One of these dopaminergic systems, the tuberoinfundibular system, secretes dopamine into the portal hypophysial vessels to inhibit prolactin secretion (Ganong, 1999a). Five different dopamine receptors have been cloned (D_1 to D_5), and several of these exist in multiple forms (Ganong, 1999b). In men, apomorphine, which stimulates both D_1 and D_2 receptors, induces erection that is unaccompanied by sexual arousal (Danjou et al, 1988). Neuroscientists have discovered that dopamine receptors (D_2 , D_3 , and D_4), nNOS, and oxytocin are coexpressed in the cell bodies of oxytocinergic neurons in the PVN and MPOA (Xiao et al, 2005; Baskerville et al, 2009). In male rats, injection of dopaminergic agonists to the PVN to stimulate D_2 , but not D_3 or D_4 , receptors, increases Ca^{2+} influx in cell bodies of oxytocinergic neurons. This increases the production of NO, which activates oxytocinergic neurotransmission in extrahypothalamic brain areas and spinal cord, leading to penile erection and yawning. The stimulation of D_4 receptors also increases Ca^{2+} influx and NO production leading to penile erection but not yawning. Nevertheless, D_4 receptors seem to play only a modest role in the pro-erectile effect (Melis and Argiolas, 2011).

Dopamine agonist in the form of sublingual apomorphine is available for the treatment of ED in many countries, but its utility is limited because of emetic side effects.

Oxytocin. Oxytocin is a neural hormone secreted by the neurons into the circulation. Oxytocin is found in the posterior pituitary gland, but because it is also found in the neurons projecting from the PVN to the brainstem and spinal cord, it can also function as a neurotransmitter. The blood level is increased during sexual activity in humans and animals. Oxytocin is a potent inducer of penile erection when injected into the central nervous system (CNS). In rats, the most sensitive brain area for the pro-erectile effect of oxytocin is the PVN of the hypothalamus. Oxytocin release after stimulation of dopamine receptors in the PVN influences the appetitive and reinforcing effects of sexual activity (Succu et al, 2007). As mentioned earlier, neurons in the paraventricular area contain NOS, and because NOS inhibitors prevent apomorphine-induced and oxytocin-induced erection, it is evident that oxytocin acts on neurons whose activity is dependent on certain levels of NO (Vincent and Kimura, 1992; Melis and Argiolas, 2011).

Nitric Oxide. NO mediates penile erection at the level of the PVN (Melis et al, 1998) and at other levels of the neural pathway supporting sexual response. The presence of NO and the soluble guanylyl cyclase needed to generate cGMP is seen throughout the human brain. The NO/cGMP pathway (see later) is affected by aging in the brain and offers a potentially significant but unexplored site for mediating the deleterious effects of age on sexual function (Ibarra et al, 2001). Reduced nNOS protein within the PVN leading to blunting of the erectile response has been reported in streptozotocin-induced diabetic rats (Zheng et al, 2007). In animals, testosterone increases NOS in the MPOA. NO increases basal and female-stimulated dopamine release, which facilitates copulation and genital reflexes. In rodents, dopamine receptor agonist-induced erections were abolished by castration, and testosterone replacement restored erectile function (Hull et al, 1999).

Serotonin. Neurons containing 5-HT have their cell bodies in the midline raphe nuclei of the brainstem and project to a portion of the hypothalamus, limbic system, neocortex, and spinal cord (Ganong, 1999a). At the present time, 5-HT receptors 1 to 7 have been cloned and characterized. Within the 5-HT₁ group are the 5-HT_{1A}, B, D, E, and F subtypes. Within the 5-HT₂ group are the 5-HT_{2A}, B, and C subtypes. There are two 5-HT₅ subtypes, 5-HT_{5A} and 5-HT_{5B} (Ganong, 1999b). General pharmacologic data indicate that 5-HT pathways inhibit copulation, but 5-HT may have both facilitatory and inhibitory effects on sexual function, depending on the receptor subtype, the receptor location, and the species investigated (de Groat and Booth, 1993). Andersson

and Wagner (1995) summarized the results of administration of selective agonists and antagonists as follows: 5-HT_{1A} receptor agonists inhibit erectile activity but assist ejaculation, stimulation of 5-HT_{2C} receptors cause erection, and 5-HT₂ agonists inhibit erection but assist seminal emission and ejaculation. Also, Steers and de Groat (1989) showed increased firing of the cavernous nerve and erection when *m*-chlorophenylpiperazine, a 5-HT_{2C} receptor agonist, was given to rats. Applying a novel 5-HT_{2C} receptor agonist (YM348) and antagonist SB242084, Kimura and colleagues (2006) confirmed the pro-erectile effect of the 5-HT_{2C} receptor stimulation in rats. In rats, 5-HT, dopamine, oxytocin, and melanocortin pathways are known to be involved in the induction of penile erections. Kimura and colleagues (2008) suggested that 5-HT_{2C} receptors in the lumbosacral spinal sites mediate not only dopamine-oxytocin-5-HT action but also melanocortin effects on penile erections and that the 5-HT pathway is located downstream from the melanocortin and the dopamine-oxytocin pathways.

5-HT is believed to be an inhibitory transmitter in the control of sexual drive (Foreman et al, 1989). Suppressed libido has been reported in patients taking fenfluramine, a 5-HT-releasing agent, but elevated libido occurred in patients taking buspirone, a 5-HT neuron suppressor (Buffum, 1982).

Norepinephrine. The cell bodies of the norepinephrine-containing neurons are located in the locus ceruleus and the A5-catecholaminergic cell group in the pons and medulla. The axons of these noradrenergic neurons ascend to innervate the paraventricular, supraoptic, and periventricular nuclei of the hypothalamus, thalamus, and neocortex. They also descend into the spinal cord and the cerebellum. Central norepinephrine transmission seems to have a positive effect on sexual function. In humans and rats, inhibition of norepinephrine release by clonidine, an α_2 -adrenergic agonist, is associated with a decrease in sexual behavior, and yohimbine, an α_2 -receptor antagonist, has been shown to increase sexual activity (Clark et al, 1985). β -Blockers have also been implicated in sexual dysfunction, probably because of their central side effects such as sedation, sleep disturbances, and depression.

Melanocortins. Melanocortin-4 receptor (MC4R), implicated in the control of food intake and energy expenditure, also modulates erectile function and sexual behavior. Evidence supporting this notion is based on several findings, as follows: (1) A highly selective nonpeptide MC4R agonist augments erectile activity initiated by electrical stimulation of the cavernous nerve in wild-type, but not MC4R-null, mice; (2) copulatory behavior is enhanced by administration of a selective MC4R agonist and is diminished in mice lacking MC4R; (3) reverse transcriptase polymerase chain reaction and non-polymerase chain reaction-based methods demonstrate MC4R expression in the rat and human penis and rat spinal cord, hypothalamus, brainstem, and pelvic ganglion (major autonomic relay center to the penis) but not in rat primary corpus cavernosum smooth muscle cells; and (4) in situ hybridization of glans tissue from the human and rat penis reveals MC4R expression in nerve fibers and mechanoreceptors in the glans. Collectively, these data implicate MC4R in the modulation of penile erectile function and provide evidence that MC4R-mediated pro-erectile responses may be activated through neuronal circuitry in spinal cord erectile centers and somatosensory afferent nerve terminals of the penis (Van der Ploeg et al, 2002).

Prolactin. Increased levels of prolactin suppress sexual function in men and experimental animals. In rats, high levels of prolactin decrease the genital reflex and disturb copulatory behavior (Rehman et al, 2000). It is suggested that the mechanism of action of prolactin is through inhibition of dopaminergic activity in the MPOA and decreased testosterone. In addition, prolactin may have a direct effect on the penis through its contractile effect on the cavernous smooth muscle (Ra et al, 1996). In a study of sexual activity of married men with ED, men with sexual inactivity were noted to have a significantly higher mean prolactin level (Paick et al, 2006) (Table 26-8).

γ -Aminobutyric Acid. γ -Aminobutyric acid (GABA) activity in the PVN provides a mechanism to balance (inhibit) pro-erectile signaling. Systemic administration or intrathecal injection at the

TABLE 26-8 Central Neurotransmitters and Their Function

NEUROTRANSMITTER	RECEPTOR AND FUNCTION
Dopamine	D1 and D4 receptor—enhances erection D2 receptor—enhances seminal emission
Serotonin (5-HT)	5-HT—inhibits sex drive and spinal sexual reflex 5-HT1A—inhibits erection, facilitates ejaculation 5-HT2C—enhances erection
Norepinephrine	Enhances sexual function
γ -aminobutyric acid	Inhibits erectile signals
Opioids	Inhibit penile erection
Cannabinoids	Inhibit sexual function
Oxytocin	Enhances appetitive and reinforcing effects of sexual activity
Nitric oxide	Mediates erection at paraventricular nucleus
Melanocortins	MCR4—enhances erection
Prolactin	Suppresses sexual function

lumbosacral level of the GABA_B receptor agonist baclofen decreased the frequency of erections in rats (Bitran and Hull, 1987). Activation of GABA_A receptors in the PVN reduced penile erection and yawning in male rats induced by apomorphine, *N*-methyl-D-aspartate, and oxytocin (Melis and Argiolas, 2002).

Opioids. Endogenous opioids are known to affect sexual function, but the mechanism of action is unclear. Injection of small amounts of morphine into the MPOA assists sexual behavior in rats. However, larger doses inhibit penile erection and yawning induced by oxytocin or apomorphine. It is suggested that endogenous opioids may exert an inhibitory control on central oxytocinergic transmission (Argiolas, 1992). Injection of morphine into the PVN of the hypothalamus prevents noncontact penile erections and impairs copulation in rats. It is speculated that intracellular NO may be involved in this process (Melis et al, 1999).

Cannabinoids. Cannabinoid CB₁ receptor activation inhibits sexual function by modulating the paraventricular oxytocinergic neurons, which mediate erection. Antagonism of CB₁ receptors in the PVN of male rats induces penile erection, which seems to involve glutamic acid and NO (Melis et al, 2004, 2006).

Smooth Muscle Physiology

In contrast to many other smooth muscles, corpus cavernosum smooth muscle is in a contracted state most of the time. In a study of myosin isoforms in smooth muscle cells in the corpus cavernosum, DiSanto and colleagues (1998) reported that their overall composition is between that in aorta and bladder smooth muscles, which generally express toniclike and phasiclike characteristics, respectively. Spontaneous contractile activity of cavernous smooth muscle has been recorded in vitro and in vivo. In a study in men, Yarnitsky and colleagues (1995) found two types of electrical activity recorded from the corpus cavernosum: spontaneous and activity induced. Berridge (2008) proposed that the rhythmic contractions of corpus cavernosum smooth muscle depend on an endogenous pacemaker driven by a cytosolic Ca²⁺ oscillator that releases Ca²⁺ from the sarcoplasmic reticulum periodically. This cytosolic oscillator can be modulated by neurotransmitters and hormones.

Molecular Mechanism of Smooth Muscle Contraction

Smooth muscle contraction is controlled by two major factors: cytosolic calcium concentration and Rho-kinase signaling (Berridge, 2008). Smooth muscle contraction can occur with or without change in membrane potential (Somlyo and Somlyo 2000; Berridge, 2008).

Cytosolic Free Calcium. Smooth muscle contraction is regulated by intracellular free calcium (Ca²⁺) acting through calmodulin. Calcium-bound calmodulin undergoes a conformational change, increasing its affinity for myosin light chain (MLC) kinase. MLC kinase is activated by binding of the calcium-calmodulin complex, leading to phosphorylation of the serine-19 residue of regulatory MLC₂₀. In the presence of adenosine triphosphate (ATP), this phosphorylation enables actin to activate the myosin ATPase and initiates cross-bridge cycling. Hydrolysis of ATP by ATPase supplies the energy for the contractile process (Fig. 26-9). The muscle contractile process ends when MLC₂₀ is dephosphorylated (inactivated) by myosin light chain phosphatase (MLCP). MLCP is a holoenzyme consisting of a type 1 phosphatase (PP1c), a myosin-targeting subunit (MYPT1), and a 20-kD subunit of unknown function (Hersch et al, 2004; Ito et al, 2004).

Rho Kinase Signaling Pathway (Calcium Sensitization Pathway). Theoretically, MLCP inhibition may lead to enhanced smooth muscle contraction. This is also termed the *calcium sensitization pathway*. The activity of MLCP can be modulated by Rho/Rho-kinase signaling (Fig. 26-10). Agonist activation causes dissociation of RhoA from Rho-guanine dissociation inhibitor and activates Rho-kinase. Phosphorylation of the regulatory subunit of MLCP by Rho-kinase inhibits phosphatase activity and enhances the contractile response (Hirano, 2007). RhoA and Rho-kinase are expressed in penile smooth muscle (Rees et al, 2002; Wang et al, 2002). The emerging consensus is that phasic contraction of penile smooth muscle is regulated by an increase in cytosolic Ca²⁺ and that tonic contraction is governed by the calcium-sensitizing pathways (Cellek et al, 2002). Several studies suggest that NO regulates RhoA/Rho-kinase activity (Bivalacqua et al, 2007; Priviero et al, 2010), and Chitale and coworkers (2001) reported that Rho-kinase antagonism stimulated rat penile erection.

Latch State: A Unique Characteristic of Smooth Muscle Contraction. Smooth muscle has the ability to maintain tension for prolonged periods with minimal energy expenditure. This efficiency has been termed the *latch* state and is critical for sustaining the “basal” tone of the smooth muscle. It has been proposed that dephosphorylated myosin remains bound to actin in the high-affinity state to help stabilize the latch state. Others have proposed that calponin participates in the latch state by simultaneously binding actin and myosin to stabilize cross-bridge interactions and slow the rate of detachment (Szymanski, 2004).

Pathways Involving Inositol 1,4,5-Triphosphate, 1,2-Diacylglycerol, and Protein Kinase C. Vasoconstrictor agonists such as norepinephrine (α_1 -adrenergic receptors), endothelin-1 (endothelin-A receptors), angiotensin II (AT1 receptors), prostaglandin F_{2 α} (FP receptors), and TXA₂ (TP receptors) bind their respective receptors to activate Gq, which stimulates phospholipase C beta. This membrane-bound enzyme hydrolyzes phosphatidylinositol 4,5-bisphosphate to liberate IP₃ and 1,2-diacylglycerol. IP₃ binds to specific receptors (IP₃ receptor) on the smooth endoplasmic reticulum to stimulate the release of Ca²⁺ from intracellular stores. Binding of IP₃ to these receptors not only activates the channel but also increases the sensitivity of the IP₃ receptor to Ca²⁺ and assists calcium-induced calcium release.

Another mechanism of increased intracellular Ca²⁺ is by permitting entry of extracellular Ca²⁺ through receptor-operated channels without a change in membrane potential (Large, 2002). Norepinephrine, endothelin, vasopressin, and angiotensin II cause the opening of Ca²⁺-permeable, nonselective cation channels.

Figure 26-9. Molecular mechanism of penile smooth muscle contraction. Norepinephrine from sympathetic nerve endings and endothelins, angiotensin II, and prostaglandin $F_{2\alpha}$ from the endothelium activate receptors on smooth muscle cells to initiate the cascade of reactions that eventually result in elevation of intracellular calcium concentrations, activation of Rho-kinase, and smooth muscle contraction. Protein kinase C is a regulatory component of the Ca^{2+} -independent, sustained phase of agonist-induced contractile responses. GDP, guanosine diphosphate; GEF, guanine nucleotide exchange factor; GTP, guanosine triphosphate.

Molecular Mechanism of Smooth Muscle Relaxation

After contraction, relaxation of the muscle follows a decrease of free Ca^{2+} in the sarcoplasm. Calmodulin dissociates from MLC kinase and inactivates it. Myosin is dephosphorylated by MLCP and detaches from the actin filament, and the muscle relaxes (Fig. 26-11) (Walsh, 1991).

Another mechanism of smooth muscle relaxation is through cyclic adenosine monophosphate (cAMP) and cGMP, which are the two major second messengers involved in smooth muscle relaxation. They activate cAMP-dependent and cGMP-dependent protein kinases, which phosphorylate certain proteins and ion channels, resulting in (1) opening of the potassium channels and hyperpolarization; (2) sequestration of intracellular calcium by the endoplasmic reticulum; and (3) inhibition of voltage-dependent calcium channels, blocking calcium influx. The consequence is a decrease in cytosolic free calcium and smooth muscle relaxation.

Cyclic Guanosine Monophosphate–Signaling Pathway. Signaling molecules in the cGMP pathway include NO, CO, hydrogen sulfide (H_2S), and natriuretic peptides.

Nitric Oxide. Because of its small size, NO can diffuse inside its target cell, where it interacts with molecules that contain iron in either a heme or an iron-sulfur complex. The most physiologically relevant receptor for NO is soluble guanylyl cyclase (sGC), and the NO-sGC-cGMP pathway is responsible for the vasorelaxation effect of many endothelium-dependent vasodilators, including histamine, estrogens, insulin, corticotropin-releasing hormone, nitrovasodilators, and acetylcholine. This pathway is also principally responsible for physiologic penile erection.

Synthesis of NO is catalyzed by NOS, which converts L-arginine and oxygen to L-citrulline and NO. NOS exists as three isoforms in mammals: nNOS and eNOS are preferentially expressed in neurons/nerves and endothelial cells, respectively, and iNOS is expressed in virtually all cell types. All three NOS isoforms have been identified in the corpus cavernosum, with nNOS and eNOS being considered responsible for initiating and sustaining erection, respectively (Hurt et al, 2002; Musicki et al, 2009). A variant of nNOS (penile nNOS) has been identified as two distinct isoforms in the penis of rats and mice (Magee et al, 1996). eNOS has an indispensable role in penile erection, and its activity and bioavailability are regulated by multiple mechanisms,

Figure 26-10. Molecular mechanism of penile smooth muscle relaxation. The intracellular second messengers mediating smooth muscle relaxation, cyclic adenosine monophosphate (cAMP) and cyclic guanosine monophosphate (cGMP), activate their specific protein kinases, which phosphorylate certain proteins to cause opening of potassium channels, closing of calcium channels, and sequestration of intracellular calcium by the endoplasmic reticulum. The resultant decrease in intracellular calcium leads to smooth muscle relaxation. Sildenafil inhibits the action of phosphodiesterase (PDE) type 5 and increases the intracellular concentration of cGMP. Papaverine is a nonspecific phosphodiesterase inhibitor. ATP, adenosine triphosphate; eNOS, endothelial nitric oxide synthase; GTP, guanosine triphosphate.

such as eNOS phosphorylation, eNOS interaction with regulatory proteins and contractile pathways, and actions of reactive oxygen species. Endothelial NO availability may be altered in vasculogenic ED. Downregulation of nNOS expression has been found in the corpus cavernosum of aging rats (Carrier et al, 1997),

castrated rats (Penson et al, 1996), and diabetic rats (Rehman et al, 1997).

Gene transfer of nNOS or eNOS to the penis has been shown to augment erectile responses in aging rats (Champion et al, 1999; Magee et al, 2002), and gene transfer of iNOS has enhanced

Figure 26-11. Immunohistochemistry of human penile tissue, showing positive phosphodiesterase type 5 staining of cavernous smooth muscle fibers (small blue arrows), nerve (yellow arrow), and blood vessel wall (red arrow) (x100).

intracavernous pressure (Chancellor et al, 2003). However, despite these encouraging results, mice with disrupted nNOS or eNOS gene have normal erectile function (Burnett et al, 1996, 2002). Compensatory mechanisms, alternative splicing of the disrupted gene (Ferrini et al, 2003), and/or other unknown mechanisms are possibly involved in the preservation of erectile function in NOS-knockout mice.

Carbon Monoxide. CO is a gaseous second messenger that occurs in biologic systems during the oxidative catabolism of heme by the HO enzyme. HO exists as constitutive (HO-2, HO-3) and inducible (HO-1) isoforms. HO-1 is upregulated in response to multiple stress stimuli. HO-1 confers protection in vitro and in vivo against oxidative cellular stress. CO regulates vascular processes, such as vessel tone, smooth muscle proliferation, and platelet aggregation, and may function as a neurotransmitter. The neurotransmitter effect of CO is dependent on the activation of guanylate cyclase by direct binding to the heme moiety of the enzyme, stimulating the production of cGMP.

Hydrogen Sulfide. L-Cysteine is a natural substrate for the synthesis of H₂S. Exogenous H₂S or L-cysteine causes relaxation of strips of human corpus cavernosum. Intracavernosal administration of either H₂S, sodium hydrosulfide (NaHS), or L-cysteine elicited penile erection in rats (d'Emmanuele di Villa Bianca et al, 2011). These observations indicate that a functional L-cysteine/H₂S pathway may be involved in mediating penile erection in men and some mammals.

Natriuretic Peptides. The natriuretic peptide family is involved in the regulation of cardiovascular homeostasis and consists of atrial (ANP), brain (BNP), and C-type (CNP) natriuretic peptides (Matsuo, 2001). ANP and BNP are ligands for the natriuretic peptide receptor NPR-A, whereas CNP is a ligand for the natriuretic peptide receptor NPR-B. Both receptors are members of the guanylyl cyclase family and are also called GC-A and GC-B.

The effects of ANP, BNP, and CNP on cGMP production and smooth muscle relaxation in isolated human and animal corpus cavernosum and in cultured cavernous smooth muscle cells have been investigated (Kim et al, 1998; Kuthe et al, 2003; Sousa et al, 2010). The results indicate that CNP is the most potent natriuretic peptide and that it relaxes the isolated cavernous smooth muscle by binding to NPR-B. However, whether CNP and NPR-B play a role in physiologic erection remains to be seen.

Guanylyl Cyclase. In mammals, seven membrane-bound (particulate) guanylyl cyclase isoforms (GC-A to GC-G) and one soluble isoform (sGC) have been identified (Andreopoulos and Papapetropoulos, 2000). Although the membrane-bound guanylyl cyclase system is not known to play a role in physiologic erection, expression of GC-B in human and rat corpus cavernosum and induction of cavernous smooth muscle relaxation by CNP (ligand for GC-B) have been demonstrated (Guidone et al, 2002; Kuthe et al, 2003).

The soluble isoform sGC plays a pivotal role in erectile function because it provides the link between NO and cGMP, which represent the extracellular and intracellular signaling molecules, respectively, in physiologic erection (Andersson, 2001). A heterodimeric protein, sGC consists of α and β subunits, each of which exists in two isoforms (α_1 , α_2 , and β_1 , β_2) that are encoded by two separate genes (Andreopoulos and Papapetropoulos, 2000). Nimmegeers and associates (2008) assessed the functional importance of the sGC $\alpha_1\beta_1$ isoform in corpus cavernosum from male sGC α_1 (–/–) and wild-type mice and concluded that the sGC $\alpha_1\beta_1$ isoform is involved in corpus cavernosum smooth muscle relaxation in response to NO and NO-independent sGC stimulators.

Protein Kinase G. PKG, also called cGMP-dependent kinase, is the principal receptor and mediator for cGMP signals. In mammals, PKG exists in two major forms, PKG-I and PKG-II, which are encoded by two separate genes. In smooth muscle, only PKG-I is expressed and exists as two splice variants (PKG-I α and PKG-I β).

cGMP and/or PKG-I may induce relaxation via activation of the plasma membrane Ca²⁺-ATPase pump, inhibition of IP₃ generation, inhibition of Rho-kinase, stimulation of MLCP, and phosphorylation of heat shock proteins (Carvajal et al, 2000; Lincoln et al, 2001). These mechanisms have been demonstrated in various cells, but their relevance to smooth muscle cells in genital tissues has not been explicitly shown.

Cavernous smooth muscle strips from PKG-I knockout mice cannot be relaxed by agents that raise cGMP levels, and these mice have a low ability to reproduce, presumably owing to ED (Hedlund et al, 2000a). This observation further affirms the essential role of the cGMP/PKG-I pathway in physiologic erection.

Cyclic Adenosine Monophosphate–Signaling Pathway. cAMP-signaling molecules include adenosine, calcitonin gene-related peptides (CGRPs), prostaglandins, and VIP.

Adenosine. Adenosine is released from various cells as a result of increased metabolic rates, and its actions on the vasculature are most prominent when oxygen demand is high (Tabrizchi and Bedi, 2001). However, the vascular response to the action of adenosine can be either relaxation or constriction, depending on which type of adenosine receptor is activated. Four adenosine receptor subtypes (A₁, A_{2A}, A_{2B}, and A₃) belonging to the GPCR superfamily have been recognized at the present time (Tabrizchi and Bedi, 2001). In general, the A₁ receptor is believed to be coupled to G_i and G_o proteins, and its activation results in inhibition of adenylyl cyclase and activation of phospholipase C, both of which lead to vasoconstriction. The A₂ receptors are coupled to the G_s proteins, and their activation stimulates adenylyl cyclase and vasorelaxation. The A₃ receptor is coupled to G_i and G_q proteins, and its activation results in the activation of phospholipase C/D and the inhibition of adenylyl cyclase, leading to vasoconstriction. The differential distribution of these adenosine receptor subtypes largely determines whether a particular vessel relaxes or contracts as a result of adenosine stimulation (Tabrizchi and Bedi, 2001). Whether adenosine plays a role in physiologic erection is unclear. Nevertheless, excessive adenosine accumulation in the penis, coupled with increased A_{2B} receptor signaling, contributes to priapism in two independent lines of mutant mice. One is adenosine deaminase-deficient mice (the animals display spontaneously prolonged penile erection), and the other is sickle cell disease transgenic mice, a well-accepted animal model for priapism (Bivalacqua et al, 2009; Dai et al, 2009).

Calcitonin Gene-Related Peptide Family. CGRP, amylin, and adrenomedullin are members of the CGRP family. These short-chain peptides are potent vasodilators released from perivascular nerve fibers. They act through the calcitonin receptor–like receptor, which belongs to the GPCR superfamily (Conner et al, 2002).

In rats, CGRP levels in the penis, bladder, kidney, testis, and adrenal gland were found to increase gradually up to maturity and then rapidly decline (Wimalawansa, 1992). In patients with ED given CGRP via intracavernous injection, a dose-related increase in penile arterial inflow (and erection) occurred (Stief et al, 1991). Adenovirus-mediated gene transfer of CGRP also enhanced erectile

responses in aged rats, apparently through an increase of cAMP levels in the corpora cavernosa (Bivalacqua et al, 2001).

Prostaglandins. Prostaglandins are a family of eicosanoids capable of initiating numerous biologic functions. The prime mode of prostaglandin action is through specific prostaglandin receptors that all belong to the GPCR family. There are at least nine known prostaglandin receptor subtypes in mice and humans and several additional splice variants with divergent carboxyl termini (Narumiya and FitzGerald, 2001). Four of the subtypes (EP1 to EP4) bind PGE₂, two (DP1 and DP2) bind PGD₂, and the other three subtypes (FP, IP, and TP) bind PGF_{2α} (FP), PGI₂ (IP), and TXA₂ (TP). On the basis of signaling attributes, the prostaglandin receptors are classified into three types. The “relaxant” receptors IP, DP1, EP2, and EP4 are coupled to an α_s-containing G protein and are capable of stimulating adenyl cyclase to increase intracellular cAMP. The “contractile” receptors EP1, FP, and TP are coupled to an α_i-containing G protein, which activates phospholipase C instead of adenyl cyclase. These contractile receptors do not signal through the cAMP pathway, and their signaling outcome is an increase of intracellular calcium. The EP3 receptor is also a contractile receptor, but it is coupled to an α_i-containing G protein that inhibits adenyl cyclase to result in a decrease of cAMP formation.

Animal and human corpora cavernosa produce several prostaglandins including PGF_{2α}, PGE₂, PGD₂, PGI₂, and TXA₂ (Moreland et al, 2001). In studies in isolated human penile tissue, different PGs have been shown to elicit different effects in human corpus cavernosum, corpus spongiosum, and cavernous artery (Hedlund and Andersson, 1985). Although PGF_{2α}, PGI₂, and TXA₂ contract the corpus cavernosum and corpus spongiosum, PGE₁ and PGE₂ (but not PGI₂) relax the corpus cavernosum and spongiosum that have been precontracted with noradrenaline or PGF_{2α}. Although PGI₂ is the predominant vasorelaxant in blood vessels, its action in the erectile tissue is either contractile or neutral. This disparity in the action of PGI₂ between blood vessels and the erectile tissue and the difference between the effects of PGI₂ and PGE₁ and PGE₂ in the erectile tissue are most likely due to differences in the distribution of prostaglandin receptors. Other studies have shown that in the corpus cavernosum, the relaxant effects of prostanoids are mediated by EP2 and/or EP4 receptors (for PGE₁ and PGE₂) but not IP receptor (for PGI₂) (Angulo et al, 2002).

Although the production of prostaglandins and the expression of prostaglandin receptors in the erectile tissue have been clearly demonstrated, their roles in physiologic erection are still undefined. The erectogenic effects of PGE₁ as a pharmaceutical agent have been extensively documented. First described in 1998, intracavernous injection of PGE₁ is one of the safest and most effective treatments for ED (Stackl et al, 1988). Transurethral application is an alternative.

Vasoactive Intestinal Peptide. The human or animal penis is richly supplied with nerves containing VIP and VIP-related peptides such as pituitary adenylate cyclase-activating polypeptide. Most of these nerves also contain immunoreactivity to NOS, and colocalization of NOS and VIP within nerves innervates the penises of both animals and humans (Andersson, 2001). Two subtypes of VIP receptors, VPAC1 and VPAC2, belonging to the GPCR family have been cloned from human and rat tissues. VPAC2, but not VPAC1, messenger RNA has been identified in cultured rat cavernous smooth muscle cells (Guidone et al, 2002). In dogs, intracavernous VIP injection has been found to induce penile erection (Juenemann et al, 1987b); in men, it has not produced rigid erection, but success rates are improved when VIP is combined with papaverine and phentolamine (Kiely et al, 1989). However, it has been shown that VIP release is not essential for neurogenic relaxation of human cavernous smooth muscle (Pickard et al, 1993), and the physiologic role of VIP in penile erection has not been resolved.

Adenylyl Cyclase. Signaling molecules in the cAMP pathway bind to and activate specific cytoplasmic membrane receptors that, through their coupled G proteins, activate adenylyl cyclases. To date, nine membrane-bound isoforms and one soluble form of mammalian adenylyl cyclase have been cloned and characterized (Patel et al, 2001). Although different membrane-bound adenylyl cyclases

are regulated differently, they all are stimulated by the GTP-bound form of the G_a subunit, and all (except AC9) are stimulated by forskolin.

In rabbits with alloxan-induced diabetes, cAMP formation in the corpus cavernosum in response to forskolin has been shown to be reduced. This suggests impaired adenyl cyclase function in diabetes mellitus (Sullivan et al, 1998).

Protein Kinase A. Protein kinase A (PKA), also called cAMP-dependent kinase, is the principal receptor for cAMP, and it mediates most of the cellular effects of cAMP by phosphorylating a wide variety of downstream targets in the cytoplasmic and nuclear compartments (Johnson et al, 2001). PKA is composed of two regulatory (R) and two catalytic (C) subunits that form a tetrameric holoenzyme R₂C₂. Binding of cAMP to the R subunits causes the holoenzyme to dissociate into an R₂(cAMP)₄ dimer and two free catalytically active C subunits. The presence of multiple C subunit genes further adds to the diversity and complexity of the various holoenzyme complexes, which differ in biochemical and functional properties as well as patterns of expression and localization. These differences among the isozymes contribute to the broad specificity of PKA in a wide variety of physiologic processes in response to cAMP signaling.

More than 100 different cellular proteins have been identified as physiologic substrates of PKA, with more than 90% (135 of 145) being phosphorylated at serine and the remainder at threonine (Shabb, 2001). The predominant target sequence (>50%) is Arg-Arg-X-Ser, in which Ser is the phosphate acceptor. Three PKA substrate proteins have been identified in penile tissue: PDEs, cAMP-responsive element-binding protein, and ATP-sensitive potassium (K_{ATP}) channel.

Cross-Activation. Increased levels of intracellular cAMP and cGMP cause the activation of cAMP-dependent and cGMP-dependent protein kinases (PKA and PKG). Each cyclic nucleotide-dependent kinase can be activated by either cAMP or cGMP, although cross-activation requires an approximately 10-fold higher concentration of cyclic nucleotide (Walsh, 1994). Although PKA and PKG may phosphorylate numerous common substrates, several lines of evidence indicate that the activation of PKG by cGMP and cAMP is the predominant mechanism by which cyclic nucleotides decrease intracellular Ca²⁺ to cause vascular smooth muscle relaxation (Lincoln et al, 1990; Jiang et al, 1992; Komalavilas and Lincoln, 1996).

Phosphodiesterase. In each episode of cyclic nucleotide signaling, the increase of intracellular cAMP or cGMP concentration is typically twofold to threefold baseline (Francis et al, 2001). Decline occurs rapidly and often during the continued presence of the signaling hormone (Francis et al, 2001). Termination of cyclic nucleotide signals is principally carried out by PDEs, which catalyze the hydrolysis of cAMP and cGMP to AMP and GMP, respectively. Feedback mechanisms that increase PDE activities and/or expression by the increased cyclic nucleotide level assist cyclic nucleotide degradation (Corbin et al, 2000; Lin et al, 2001a, 2001b).

The superfamily of mammalian PDEs consists of 11 families (PDE1 to PDE11) that are encoded from 21 distinct genes (Lin et al, 2003; Montorsi et al, 2004). Each PDE gene usually encodes more than one isoform through alternative splicing or from alternative gene promoters. PDE1, PDE3, PDE4, PDE7, and PDE8 are multi-gene families, whereas PDE2, PDE5, PDE9, PDE10, and PDE11 are unigene families. PDE1, PDE2, PDE3, PDE10, and PDE11 hydrolyze cAMP and cGMP; PDE4, PDE7, and PDE8 hydrolyze cAMP; and PDE5, PDE6, and PDE9 hydrolyze cGMP.

With the exception of PDE6, which is specifically expressed in photoreceptor cells, all PDEs have been identified in the corpus cavernosum (Küthe et al, 2001). However, there is ample evidence that PDE5 is the principal PDE for the termination of cavernous cGMP signaling (Fig. 26-12), and inhibition of the cGMP-catalytic activity by PDE5 inhibitors is highly effective in treating ED.

PDE5 also appears to play a role in erection, as demonstrated by the erectogenic effect of a PDE3-specific inhibitor, milrinone (Küthe et al, 2002). Although direct inhibition of PDE5 is the main mechanism through which sildenafil exerts its erectogenic effect, it has been shown that sildenafil also significantly increases cAMP

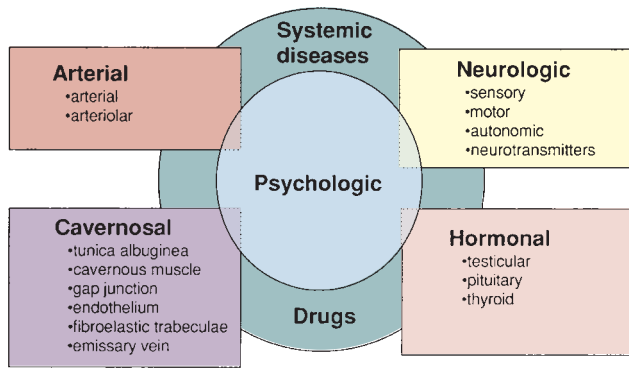

Figure 26-12. Functional classification of impotence. It is unlikely for impotence in an individual patient to derive solely from one source. Most cases have a psychogenic component of varying degree, and systemic diseases and pharmacologic effects can be concomitant and causative. (Modified from Carrier S, Brock G, Kour NW, et al. Pathophysiology of erectile dysfunction. Urology 1993;42:468–81, with permission of Excerpta Medica, Inc.)

concentration in isolated human cavernous tissue strips (Stief et al, 2000). This effect is thought to involve PDE3 because cGMP, which is accumulated as a result of PDE5 inhibition by sildenafil, is capable of preventing cAMP degradation by competing for the same catalytic sites on the PDE3 molecules (Francis et al, 2001). This attenuating effect of cGMP on the cAMP-catalytic activity of PDE3 is also believed to explain why inhibition of PKG could suppress the relaxing effect of forskolin in isolated human cavernous smooth muscle (Uckert et al, 2004).

Ion Channels. In general, there are four major types of ion channels: (1) external ligand-gated, which open to a specific extracellular molecule (e.g., acetylcholine); (2) internal ligand-gated, which open or close in response to an intracellular molecule (e.g., ATP); (3) voltage-gated, which open in response to a change in membrane potential (e.g., sodium, potassium, and calcium channels); and (4) mechanically gated, which open in response to mechanical pressure.

Smooth muscle has neither a T-tubule system nor a well-developed sarcoplasmic reticulum. Extracellular calcium plays an important role, and calcium must enter the cytoplasm through the plasma membrane during an action potential. Three transmembrane proteins are known to regulate calcium inflow and outflow: Calcium channels are the major inflow regulators, whereas the calcium-sodium exchanger and calcium-ATPase regulate calcium exit from muscle cells. The presence of voltage-dependent L-type calcium channels (long-duration current, slow calcium channel) in isolated cavernous smooth muscle and cultured muscle cells has been documented. Christ and colleagues (1993a) reported that both calcium influx through calcium channels and mobilization of intracellular calcium stores are involved during phenylephrine-induced and endothelin-induced contraction.

Studies have shown at least four types of potassium channel subtypes in the cavernous smooth muscle: (1) calcium-sensitive potassium channel (e.g., maxi-K); (2) metabolically regulated potassium channels (K_{ATP}); (3) delayed rectifier; and (4) fast transient A current (Christ et al, 1993a; Fan et al, 1995). The calcium-sensitive potassium channels may be involved in cAMP-mediated smooth muscle relaxation. Decreased intracytosolic potassium and altered potassium conductance have been shown to occur in corpus cavernosum smooth muscle treated with acetylcholine and sodium nitroprusside (Seftel et al, 1996). The movement of positively charged K^+ out of the cell causes hyperpolarization and relaxation of smooth muscle (Andersson, 2001).

Calcium-activated chloride channels on the smooth muscle cells of corpus cavernosum are thought to be involved in the maintenance of spontaneous tone and the contractile response to adrenaline and other agonists (Fan et al, 1999; Chu and Adaikan, 2008).

Hyperpolarization of Smooth Muscle Cells. Hyperpolarization causes closure of voltage-dependent calcium channels, a decrease in the intracellular free calcium concentration, and relaxation of the smooth muscle. One of the hyperpolarization mechanisms is through the opening of potassium channels. The opening of ATP-sensitive K^+ channels (K_{ATP}) and Ca^{2+} -activated K^+ channels (K_{Ca}) causes hyperpolarization and relaxation of vascular smooth muscle. These two types of channels are present in human corpus cavernosum smooth muscle (Christ et al, 1993b), and pharmacologic stimulation of K_{ATP} channels induces penile smooth muscle relaxation (Venkateswarlu et al, 2002). PNU-83757, an opener of K_{ATP} channels, has been shown to induce erection when administered intracavernously to patients with ED (Vick et al, 2002). The opening of large-conductance K_{Ca} channels, also known as maxi-K, has been found to hyperpolarize and relax human corpus cavernosum (Spekter et al, 2002). The opening of K^+ channels can be stimulated by PKA, PKG, or cGMP.

Hyperpolarization of penile smooth muscle is also important in endothelium-dependent relaxation of human penile arteries, in which significant relaxation remains despite blockade of NO and prostaglandin synthesis (Angulo et al, 2003b). This activity has been attributed to EDHF, which opens K_{Ca} channels and produces hyperpolarization and vasodilation. The nature of EDHF remains undetermined.

Molecular Oxygen as a Modulator of Penile Erection. The PO_2 level of cavernous blood in the flaccid state is similar to that of venous blood (≈ 35 mm Hg). During erection, the large inflow of arterial blood increases PO_2 to approximately 90 mm Hg (Sattar et al, 1995). Molecular oxygen is a substrate, together with L-arginine, for the synthesis of NO by NOS. In the flaccid state, the low oxygen concentration inhibits NO synthesis; during erection, the higher level of substrate induces NO synthesis. It has been estimated that the minimal concentration of oxygen in the cavernous bodies necessary to reach full NOS activity is 50 to 60 mm Hg (Kim et al, 1993).

Similarly, prostaglandin H synthase is also an oxygenase (cyclooxygenase) and uses oxygen as substrate for the synthesis of prostanooids. Production of PGE_1 has been shown to be inhibited in flaccidity and stimulated during erection. Endothelin synthesis is also modulated by oxygen: A low oxygen concentration promotes production, whereas a high concentration inhibits it.

Intercellular Communication. During erection and detumescence, communication should exist among cavernous smooth muscles to mediate synchronized relaxation and contraction (Christ et al, 1991). Several studies have demonstrated the presence of gap junctions in the membrane of adjacent muscle cells. These intercellular channels allow exchange of ions such as calcium and second-messenger molecules (Christ et al, 1993a). The major component of gap junctions is connexin-43, a membrane-sparing protein of less than 0.25 μm that has been identified between smooth muscle cells of human corpus cavernosum (Campos de Calvalho et al, 1993). Cell-to-cell communication through these gap junctions most likely explains the synchronized erectile response, although their pathophysiologic impact is still unclear.

Intracavernous Tissue Architecture

The trabeculae of the corpora cavernosa provide the structural support and regulatory mechanism for the endothelial-lined sinusoidal spaces as well as the conduit for blood vessels and nerves. Relaxation of the trabeculae allows the expansion and filling of the sinusoids by the incoming blood, whereas “recoil” of the trabeculae expels blood to the emissary veins and returns the penis to a flaccid state. In 24 men undergoing penile prosthesis implantation for severe ED, Nehra and colleagues (1996) categorized the smooth muscle content of the corpus cavernosum into four groups—high (39% to 42%), intermediate (30% to 37%), low (13% to 29%), and normal (42% to 50%)—and reported that increasing degree of venous leakage correlates with decreasing muscle content. In specimens from six men who died of nongenital causes, Costa and colleagues (2006) showed that the major constituents of the

trabeculae are collagen fibers (40.8%), smooth muscle (40.4%), and elastic fibers (13.2%). In seven men undergoing penile prosthesis implantation, the three components were composed of collagen fibers (41.6%), smooth muscle (42%), and elastic fibers (9.1%); the only significant change in men with ED compared with normal men was a reduction of elastic fibers. From these two reports, it seems likely that the histologic changes associated with ED consist primarily of decline in either smooth muscle or elastic fibers.

The complex architecture of the penis is maintained by the dynamic expression and interaction of numerous trophic factors. One is sonic hedgehog (SHH), which plays a key role in regulating vertebrate organogenesis, such as the growth of digits on limbs and organization of the brain. SHH remains important in adults. It controls cell division of adult stem cells and has been implicated in development of some cancers. SHH has been identified in the penis; inhibition of SHH in adult rats leads to rapid atrophy and disorganization of the corpus cavernosum (Podlasek et al, 2003, 2005). In addition, SHH has been shown to stimulate the expression of vascular endothelial growth factor (VEGF) and NOS in the penis (Podlasek et al, 2005) (Table 26-9).

KEY POINTS: SMOOTH MUSCLE PHYSIOLOGY

- Relaxation of the cavernous smooth muscle is the key to penile erection.
- NO released by nNOS contained in the terminals of the cavernous nerve initiates the erection process, whereas NO released from eNOS in the endothelium helps maintain erection.
- On entering the smooth muscle cells, NO stimulates the production of cGMP.
- cGMP activates PKG, which opens the potassium channels and closes the calcium channels.
- Low cytosolic calcium favors smooth muscle relaxation.
- The smooth muscle regains its tone when cGMP is degraded by PDE.

TABLE 26-9 Key Molecules Involved in Physiologic Regulation of Cavernous Smooth Muscle

CONTRACTION	
NAME	FUNCTION
High cytosolic calcium	Binds calmodulin to activate MLC kinase
MLC kinase	Converts MLC to active form, MLCP
Phosphorylated MLC (MLCP)	Cycling of myosin cross-bridges along actin results in muscle contraction
MLCP	Dephosphorylates MLCP to inactive form, MLC
Rho-kinase	Inhibits MLC phosphatase to enhance contraction (calcium sensitization pathway)
RELAXATION	
NAME	FUNCTION
Nitric oxide	Binds soluble guanylyl cyclase to produce cGMP
cGMP	Activates protein kinase G
Protein kinase G	Opens potassium channels and closes calcium channels
Low cytosolic calcium	Calcium dissociates from calmodulin, muscle relaxes

cGMP, cyclic guanosine monophosphate; MLC, myosin light chain; MLCP, myosin light chain phosphatase.

PATHOPHYSIOLOGY OF ERECTILE DYSFUNCTION

"The Penis Poem"

*My nookie days are over, My pilot light is out.
What used to be my sex appeal, Is now my water spout.
Time was when, on its own accord, From my trousers it would
spring.
But now I've got a full time job, To find the gosh darn thing.
It used to be embarrassing, The way it would behave.
For every single morning, It would stand and watch me shave.
Now as old age approaches, It sure gives me the blues.
To see it hang its little head, And watch me tie my shoes!!*

– Willie Nelson

Incidence and Epidemiology

The increasing incidence of impotence with age was noted by Kinsey and colleagues in 1948: only 1 of 50 men at age 40 years, but 1 in 4 men by age 65. In 1990, Diokno and colleagues reported that 35% of married men 60 years old and older experienced erectile impotence.

Modern probability sampling techniques were used by two surveys obtaining prevalence data of ED in the United States: the Massachusetts Male Aging Study (MMAS) and the National Health and Social Life Survey (NHSLs). The MMAS consisted of 1709 non-institutionalized men between the ages of 40 and 70 years living in the greater Boston area first surveyed between 1987 and 1989 and resurveyed between 1995 and 1997 (Feldman et al, 1994; Johannes et al, 2000). Extensive physiologic measures, demographic information, and self-reported ED status (nine items related to potency on a questionnaire) were components of this report. The MMAS was the first cross-sectional, community-based, random-sample, multi-disciplinary epidemiologic survey on ED and its physiologic and psychosocial correlates in men in the United States. From the prevalence rates reported in the MMAS study, between the ages of 40 and 70 years, the probability of complete ED increased from 5.1% to 15%, the probability of moderate dysfunction increased from 17% to 34%, and the probability of mild dysfunction remained constant at about 17%.

The NHSLs was a national probability survey of men (N = 1410) and women between the ages of 18 and 59 years living in households in the United States in 1992 (Laumann et al, 1999) and was principally a broad-ranging inquiry into sexual practices and beliefs within that age group. The survey collected only limited information on sexual function broadly defined. The following prevalence rates for ED were reported (responses to questions regarding obtaining and maintaining erection): 7% for ages 18 to 29 years, 9% for ages 30 to 39, 11% for ages 40 to 49, and 18% for ages 50 to 59.

Regarding worldwide prevalence of ED, 24 international studies were reported between 1993 and 2003 (Lewis et al, 2004). All studies that were stratified by age showed an increasing prevalence of ED. For men younger than age 40, the rate was 1% to 9%; from 40 to 59, it ranged from 2% to 9% to 20% to 30%, with some studies showing marked differences between the 40 to 49 and the 50 to 59 age groups. The 50 to 59 age groups showed the greatest range of reported prevalence rates. For the 60 to 69 age group, most of the world showed a high rate (20% to 40%), with some showing increases after age 65 except for the Scandinavian reports, in which the 70s and older were the time of major rate change. Almost all of the reports showed high prevalence rates for men in their 70s and 80s, ranging from 50% to 75%.

Incidence Studies

The MMAS (Johannes et al, 2000) is the only longitudinal study conducted in the United States (1987-1989 and 1995-1997). Analyses were performed on 847 of the 1297 men without ED at baseline (1987-1989) and with follow-up information from 1995 to 1997. The average age of these men at baseline was 52.2 years (range 40 to 69 years). From this group of men, the crude incidence rate of impotence in white men in the United States was 25.9 cases/1000

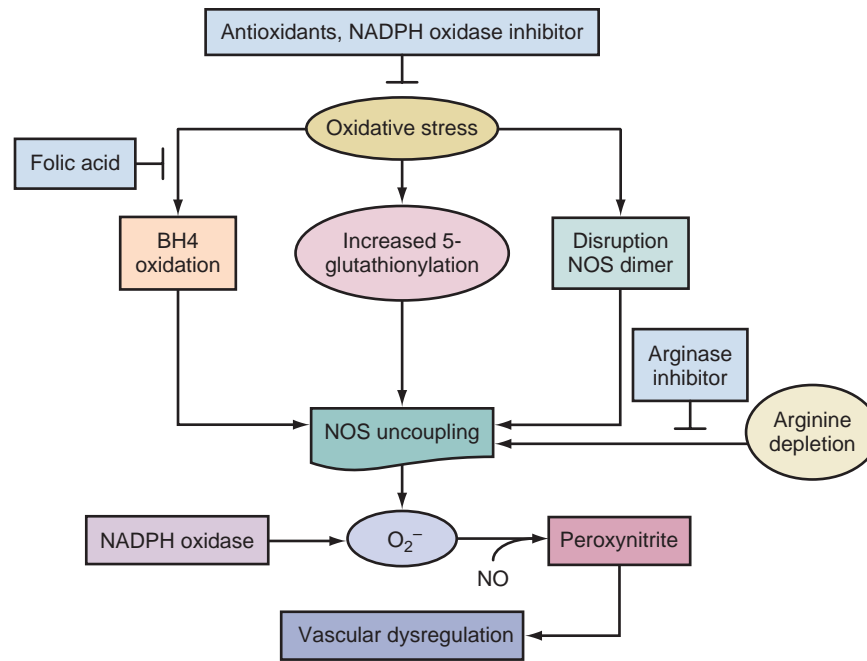

Figure 26-13. Factors contributing to nitric oxide synthase (NOS) uncoupling and the potential inhibitors. BH4, tetrahydrobiopterin; NADPH, reduced nicotinamide adenine dinucleotide phosphate.

man-years (95% confidence interval 22.5 to 29.9). The annual incidence rates increased with each decade (per 1000 man-years): 12.4 cases for 40 to 49 years, 29.8 cases for 50 to 59 years, and 46.4 cases for 60 to 69 years. Age-adjusted risk (per 1000 man-years) of ED was higher for men with diabetes mellitus (50.7 cases), treated heart disease (58.3 cases), and treated hypertension (42.5 cases). By using these data and the known population of the United States, it was estimated that, for white men, the new cases in the 40 to 69 age group would be 617,715 per year (Lewis et al, 2000). Rates reported from Europe and Brazil also suggest an incidence of 25 to 30 per 1000 man-years (Moreira et al, 2003; Schouten et al, 2005). A study using a validated questionnaire in a random sample of 2213 men conducted in Olmsted County, Minnesota, from 1996 to 2004 revealed that the five sexual function domains change together over time in this community-based cohort. Erectile function, ejaculatory function, and sexual drive decrease over time with greater rates of decline for older men. However, older men are less likely to perceive these declines as a problem and are less likely to express dissatisfaction referable to them (Gades et al, 2009).

Risk Factors

Common risk factor categories associated with sexual dysfunction include the following: general health status, diabetes mellitus, cardiovascular disease, concurrence of other genitourinary disease, psychiatric/psychological disorders, other chronic diseases, and sociodemographic conditions. In a study of race/ethnicity and socioeconomic status in 2301 men 30 to 79 years old from Boston, it was reported that men in the low socioeconomic status category had a greater than twofold increase in risk of ED (adjusted odds ratio 2.26, 95% confidence interval 1.39, 3.66). The increased risk of ED in black and Hispanic men in this study was thought to be associated with differences in socioeconomic status rather than biologic factors (Kupelian et al, 2008).

For ED, smoking, medications, and hormonal factors also serve as well-defined risk factors. In men, diabetes has been associated with a greater prevalence of decreased desire and orgasmic dysfunction as well as ED. A higher odds ratio is seen with insulin-dependent diabetes mellitus; diabetes present for more than 10

years; fair or poor control based on glycosylated hemoglobin; management by means other than diet; a history of diabetes-related arterial, renal, or retinal disease and neuropathy; and concurrent cigarette smoking. Endothelial dysfunction is a condition present in many cases of ED, and there are common etiologic pathways for other vascular disease states (Lewis et al, 2004).

Classification

Many classifications have been proposed (Fig. 26-13). Some are based on the cause (diabetic, iatrogenic, traumatic), and some are based on the neurovascular mechanism (failure to initiate [neurogenic], failure to fill [arterial], and failure to store [venous]) (Goldstein, personal communication, 1990). A classification recommended by the International Society of Impotence Research is shown in Box 26-1 (Lizza and Rosen, 1999).

Psychogenic

Previously, psychogenic impotence was believed to be the most common, thought to affect 90% of impotent men (Masters and Johnson, 1965). This belief has given way to the realization that ED is usually a mixed condition that may be predominantly functional or physical.

Sexual behavior and penile erection are controlled by the hypothalamus, limbic system, and cerebral cortex. Stimulatory or inhibitory messages can be relayed to the spinal erection centers to assist or inhibit erection. Two possible mechanisms have been proposed to explain the inhibition of erection in psychogenic dysfunction: direct inhibition of the spinal erection center by the brain as an exaggeration of the normal suprasacral inhibition (Steers, 2000) and excessive sympathetic outflow or elevated peripheral catecholamine levels, which may increase penile smooth muscle tone to prevent its necessary relaxation. Animal studies demonstrate that the stimulation of sympathetic nerves or systemic infusion of epinephrine causes detumescence of the erect penis (Diederichs et al, 1991a, 1991b). Clinically, higher levels of serum norepinephrine have been reported in patients with psychogenic ED than in normal controls or patients with vasculogenic ED (Kim and Oh, 1992).

BOX 26-1 Classification of Male Erectile Dysfunction**ORGANIC**

- I. Vasculogenic
 - A. Arteriogenic
 - B. Cavemosal
 - C. Mixed
- II. Neurogenic
- III. Anatomic
- IV. Endocrinologic

PSYCHOGENIC

- I. Generalized
 - A. Generalized unresponsiveness
 - 1. Primary lack of sexual arousability
 - 2. Aging-related decline in sexual arousability
 - B. Generalized inhibition
 - 1. Chronic disorder of sexual intimacy
- II. Situational
 - A. Partner-related
 - 1. Lack of arousability in specific relationship
 - 2. Lack of arousability owing to sexual object preference
 - 3. High central inhibition owing to partner conflict or threat
 - B. Performance-related
 - 1. Associated with other sexual dysfunction (e.g., rapid ejaculation)
 - 2. Situational performance anxiety (e.g., fear of failure)
 - C. Psychological distress or adjustment related
 - 1. Associated with negative mood state (e.g., depression) or major life stress (e.g., death of partner)

Bancroft and Janssen (2000) theorized that male sexual response depends on the balance between excitatory and inhibitory impulses within the CNS. One example is the high prevalence of sexual dysfunction/ED in men with psychiatric disorders. Mosaku and Ukpong (2009) surveyed patients (mean age 39.6, standard deviation 11.6 years) with a diagnosis of schizophrenia, bipolar affective disorder, recurrent depressive disorder, and/or substance use disorder with mean duration of illness of 10.24 years (standard deviation 8.2 years) who were attending a psychiatry clinic. In this population, the prevalence of ED was 83%; older age, unmarried status, use of medications, and the presence of comorbid medical conditions were significantly predictive of ED.

Neurogenic

It has been estimated that 10% to 19% of ED is neurogenic. If one includes iatrogenic causes and mixed ED, the prevalence is likely much higher. The presence of a neurologic disorder or neuropathy does not exclude other causes, and confirming that ED is neurogenic can be challenging. Because erection is a neurovascular event, any disease or dysfunction affecting the brain, spinal cord, and cavernous or pudendal nerves can induce dysfunction.

As discussed earlier, the MPOA, PVN, and hippocampus have been regarded as important integration centers for sexual drive and erection (Sachs and Meisel, 1988), and pathologic processes in these regions, such as Parkinson disease, stroke, encephalitis, or temporal lobe epilepsy, are often associated with ED. The effect of parkinsonism may result from the imbalance of the dopaminergic pathways (Chaudhuri and Schapira, 2009). Other brain lesions associated with ED are tumors, dementias, Alzheimer disease, multiple system atrophy, and trauma. In studies of sexual function in men after stroke, lack of sexual desire was found to be common (Jung et al, 2008). ED is more prevalent in patients who have cerebrovascular accident lesions in the thalamic area (Jeon et al, 2009).

In men with a spinal cord injury, the nature, location, and extent of the injury largely determine erectile function. In addition to ED, these men may have impaired ejaculation and orgasm. Reflexogenic erection is preserved in 95% of patients with complete upper cord lesions but in only about 25% of patients with complete lower cord lesions (Biering-Sørensen and Sønksen, 2001). Sacral parasympathetic neurons are important in the preservation of reflexogenic erection, although the thoracolumbar pathway may compensate for sacral loss through synaptic connections. In these patients, minimal tactile stimulation can trigger erection, albeit of short duration and requiring continuous stimulation. Other disorders at the spinal level (e.g., spina bifida, disk herniation, syringomyelia, tumor, transverse myelitis, and multiple sclerosis) may affect the afferent or efferent neural pathway in a similar manner.

Because of the close relationship between the cavernous nerves and the pelvic organs, the incidence of iatrogenic impotence from pelvic surgical procedures is reportedly high: radical prostatectomy, 43% to 100% (Walsh and Donker, 1982; Borchers et al, 2006), and abdominal perineal resection, 15% to 100% (Weinstein and Roberts, 1977).

An improved understanding of the neuroanatomy of the pelvic and cavernous nerves (Walsh and Donker, 1982) has resulted in modified surgery for cancer of the rectum, bladder, and prostate, producing a lower incidence of iatrogenic impotence. For example, the introduction of nerve sparing has reduced the incidence of impotence to 30% to 50% after radical prostatectomy (Catalona and Bigg, 1990; Quinlan et al, 1991) and less than 10% after radical rectal surgery (Liang et al, 2008).

In cases of pelvic fracture, ED can be a result of cavernous nerve injury or vascular insufficiency or both. In men with posterior urethral injury, early realignment has been associated with better potency preservation rate relative to delayed anastomosis (ED rate 34% vs. 42%) (Mouraviev et al, 2005). In diabetics, impairment of neurogenic and endothelium-dependent relaxation results in inadequate NO release (Saenz de Tejada et al, 1989a). Because autonomic penile innervation cannot be tested directly, clinicians should be cautious in diagnosing neurogenic ED. A corpus cavernosum electromyograph has been developed and refined for diagnosis of various conditions affecting the penis (including autonomic neuropathy), but the clinical utility of this device is still under investigation (Guiliano and Rowland, 2013).

A decrease in penile tactile sensitivity with increasing age was also reported by Rowland and colleagues (1993). Sensory input from the genitalia is essential to achieve and maintain reflexogenic erection, and the input becomes even more important when older people gradually lose psychogenic erection. Sensory evaluation should be an integral part of the evaluation for ED in all patients with or without an apparent neurologic disorder.

Endocrinologic

Hypogonadism is a frequent finding in impotent patients. Androgens influence the growth and development of the male reproductive tract and secondary sex characteristics; their effects on libido and sexual behavior are well established. In a review of published articles from 1975 to 1992, Mulligan and Schmitt (1993) concluded that testosterone (1) enhances sexual interest, (2) increases the frequency of sexual acts, and (3) increases the frequency of nocturnal erection but has little or no effect on fantasy-induced or visually stimulated erections. Granata and colleagues (1997) reported that the threshold level of testosterone for normal nocturnal erections is about 200 ng/dL. In a population-based, observational survey conducted in the Boston area, Araujo and colleagues (2007) reported a 5.6% prevalence of symptomatic androgen deficiency in men between the ages of 30 and 79 years, with older men at greater risk. Prevalence of symptoms was as follows: low libido, 12%; ED, 16%; osteoporosis/fracture, 1%; and two or more nonspecific symptoms, 20%. However, many men with low testosterone levels are asymptomatic. In a study of patients presenting with ED, Köhler and colleagues (2008) reported androgen

deficiency symptoms in 47% of men with testosterone levels of less than 200 ng/dL, 33% of men with levels less than 300 ng/dL, 23% of men with levels less than 346 ng/dL, and 7% of men with levels less than 400 ng/dL. Age, the presence of uncontrolled diabetes, high total cholesterol, and anemia all correlated with significantly decreased testosterone levels in men with ED. In another report from the same group, waist circumference was noted to be the most important predictor of low testosterone and symptomatic androgen deficiency (Hall et al, 2008). In men with a body mass index (BMI) of more than 30 kg/m², total testosterone was subnormal in 57.5%, and free testosterone subnormal in 35.6%. Most of these men had isolated hypogonadotropic hypogonadism (Hofstra et al, 2008). In a comprehensive literature review, Traish and colleagues (2009) noted that low testosterone precedes elevated fasting insulin, glucose, and hemoglobin A_{1c} values in men who develop diabetes, suggesting that hypogonadism may be a sentinel event in the development of diabetes. The authors further suggested that androgen deficiency is associated with insulin resistance, type 2 diabetes, metabolic syndrome, and increased deposition of visceral fat. Visceral fat may serve as an endocrine organ, producing inflammatory cytokines and promoting endothelial dysfunction and vascular disease.

The mechanism of androgen's effect has been examined by several investigators. Beyer and González-Mariscal (1994) reported that testosterone and dihydrotestosterone (DHT) are responsible for male pelvic thrusting and estradiol or testosterone is responsible for female pelvic thrusting during copulation. Androgens have beneficial effects on endothelial cells and smooth muscle cells: Androgens promote endothelial cell survival, reduce endothelial expression of proinflammatory markers, and inhibit proliferation and intimal migration of vascular smooth muscle cells. Low androgen levels are associated with apoptosis of endothelial cells and smooth muscle cells. Low androgen levels also impair proliferation, migration, and homing of endothelial progenitor cells as well as myogenic differentiation of mesenchymal progenitor cells (Mirone et al, 2009; Traish and Galoosian, 2013). Testosterone and DHT may also relax penile artery and cavernous smooth muscle through their nongenomic effects (Waldkirch et al, 2008). In rats, castration has been reported to decrease arterial flow, induce venous leakage, and reduce the erectile response to stimulation of the cavernous nerve by about 50% (Mills et al, 1994; Penson et al, 1996). Castration also increases α -adrenergic responsiveness of penile smooth muscle (Traish et al, 1999). Clinically, many men receiving long-term androgen ablation therapy for prostate cancer have reported poor libido and ED.

Any dysfunction of the hypothalamic-pituitary axis can result in hypogonadism. Hypogonadotropic hypogonadism can be congenital or caused by a tumor or injury. Hypergonadotropic hypogonadism may result from a tumor, injury, surgery, or mumps orchitis.

Hyperprolactinemia, whether secondary to a pituitary adenoma or drugs, results in both reproductive and sexual dysfunction. Symptoms may include loss of libido, ED, galactorrhea, gynecomastia, and infertility. Hyperprolactinemia is associated with low circulating levels of testosterone, which appear to be secondary to inhibition of gonadotropin-releasing hormone secretion by the elevated prolactin levels (Leonard et al, 1989). In a study of subjects consulting for sexual dysfunction, prolactin in the lowest quartile levels was noted to be associated with metabolic syndrome and arteriogenic ED as well as with premature ejaculation and anxiety symptoms (Corona et al, 2009).

ED may also be associated with hyperthyroidism and hypothyroidism. Hyperthyroidism is commonly associated with diminished libido (which may be caused by the increased circulating estrogen levels) and less often with ED. In hypothyroidism, low testosterone secretion and elevated prolactin levels contribute to ED.

Arteriogenic

Atherosclerotic or traumatic arterial occlusive disease of the hypogastric-cavernous-helicine arterial tree can decrease the

perfusion pressure and arterial flow to the sinusoidal spaces, increasing the time to maximal erection and decreasing the rigidity of the erect penis. In most patients with arteriogenic ED, the impaired penile perfusion is a component of the generalized atherosclerotic process. Common risk factors associated with arterial insufficiency include hypertension, hyperlipidemia, cigarette smoking, diabetes mellitus, blunt perineal or pelvic trauma, and pelvic irradiation (Feldman et al, 1994; Martín-Morales et al, 2001). Shabsigh and colleagues (1991) reported that abnormal penile vascular findings increased significantly as the number of risk factors for ED increased. On arteriography, bilateral diffuse disease of the internal pudendal, common penile, and cavernous arteries has been found in ED patients with atherosclerosis. Focal stenosis of the common penile or cavernous artery is most often seen in young patients who have sustained blunt pelvic or perineal trauma (Levine et al, 1990). Long-distance cycling is also a risk factor for vasculogenic and neurogenic ED. There is a significant relationship between cycling-induced perineal compression leading to vascular, endothelial, and neurogenic dysfunction in men and the development of ED (Sommer et al, 2010). Nevertheless, ED does not commonly occur in men who engage in recreational bicycle riding (Kim et al, 2011).

ED and cardiovascular disease share the same risk factors such as hypertension, diabetes mellitus, hypercholesterolemia, and smoking (Feldman et al, 1994; Martín-Morales et al, 2001). Lesions in the pudendal arteries are much more common in men with ED than in the general population of similar age. Natural remission and progression occur in a substantial number of men with ED. The association of BMI with remission and progression and the association of smoking and health status with progression offer potential avenues for facilitating remission and delaying progression using lifestyle intervention (Travison et al, 2007).

Cardiovascular Diseases. High prevalence of ED has been reported in men with coronary, cerebral, and peripheral vascular diseases (Bener et al, 2008; Chai et al, 2009). Among men with coronary arterial disease, the prevalence of ED increases as the severity of coronary arterial lesions increases (Montorsi et al, 2006). Several studies reported an association between ED and cardiovascular disease. The link between these conditions might reside in the interaction between androgens, chronic inflammation, and cardiovascular risk factors that determines endothelial dysfunction and atherosclerosis, resulting in disorders of penile and coronary circulation. Because penile artery size is smaller compared with coronary arteries, the same level of endothelial dysfunction causes a more significant reduction of blood flow in erectile tissues compared with that in coronary circulation. ED could be an indicator of systemic endothelial dysfunction (Gandaglia et al, 2014). In patients with chronic coronary disease who also had ED, onset of sexual dysfunction occurred before coronary artery disease onset in 93%, with a mean time interval of 24 months (range 12 to 36 months) (Montorsi et al, 2006). These data have led some authors to advocate screening for ED as a means to identify men at risk for cardiovascular disease (Gandaglia et al, 2014).

Hyperlipidemia. ED has been associated with a high prevalence of hyperlipidemia and coronary heart disease (Roumeguere et al, 2003). Hypercholesterolemia at baseline was also shown to be a predictor of subsequent ED over the course of 25 years in 570 male patients included in the Rancho Bernardo Study (Fung et al, 2004). A survey of 1899 men 30 to 79 years old in the Boston area did not show an association between untreated hyperlipidemia and ED (Hall et al, 2009).

The effect of hypercholesterolemia on erectile function has been studied in different experimental models. In hypercholesterolemic rabbits, examination of the corpus cavernosum ultrastructure revealed an early atherosclerotic process in the sinusoids (Kim et al, 1994). Although the endothelial NO/cGMP pathway is impaired in this model, neuronal vasodilation does not appear to be affected (Azadzoi et al, 1998). The NO/cGMP pathway effect likely is due to increased superoxide production (Kim et al, 1997) or endogenous NOS inhibitors such as NG-monomethyl-L-arginine monoacetate and asymmetrical dimethylarginine (ADMA).

L-Arginine supplementation reverses impairment of endothelium-dependent relaxation (Azadzo et al, 1998). VEGF is an important angiogenic factor for maintenance of endothelial health. Ryu and colleagues (2006) reported that VEGF and VEGF receptor 2 are downregulated in the corporeal tissue of rats eating a 4% cholesterol diet for 3 months. Xie and colleagues (2005) noted that levels of VEGF mRNA are reduced with subsequent observation of impaired endothelium-dependent relaxation in rabbits fed with a 1% cholesterol diet.

In a more severe ischemic experimental model, rabbits underwent balloon de-endothelialization of the iliac arteries followed by a high-cholesterol diet (Azadzo et al, 1992). The rabbits developed penile arterial insufficiency and veno-occlusive dysfunction owing to decreased expandability of the cavernous smooth muscle (Azadzo et al, 1997; Nehra et al, 1998). Changes in iliac and penile vasculature were noted, associated with decreased NOS activity and reduced endothelium-dependent and neurogenic NO-mediated relaxation of the cavernous tissue (Azadzo et al, 1999). As a result of the impaired NO activity, production of contractile thromboxane and prostaglandin increased, leading to potentiation of neurogenic contractions of the cavernous smooth muscle (Azadzo et al, 1998, 1999).

In large arteries in rabbits, oxidized low-density lipoproteins inhibited endothelium-dependent NO-mediated relaxation (Murohara et al, 1994). Enhanced corpus cavernosum muscle contractility by oxidized low-density lipoproteins has also been reported by Ahn and colleagues (1999).

Obesity. In a U.S. study of community-dwelling men 65 years old and older, Garimella and associates (2013) reported prevalence of complete ED of 42% in men who completed MMAS scale (N = 4108). In sexually active men who completed the five-item International Index of Erectile Function (IIEF-5) questionnaire (N = 1659) the prevalence of moderate to severe ED was 56%. In multivariate-adjusted analyses, high body weight, BMI, and total body fat percentage were independently associated with greater prevalence of moderate to severe and complete ED.

Perivascular adipose tissue (PVAT) is recognized as an active contributor to vascular function. Adipocytes and stromal cells contained within PVAT are sources of molecules with varied paracrine effects on the underlying smooth muscle and endothelial cells, including adipokines, cytokines, reactive oxygen species, and gaseous compounds. In obesity and diabetes, the expanded PVAT contributes to vascular insulin resistance. PVAT-derived cytokines may influence key steps of atherogenesis. The physiologic anticontractile effect of PVAT is severely diminished in hypertension. Above all, a common denominator of PVAT dysfunction in all these conditions is immune cell infiltration, which triggers the subsequent inflammation, oxidative stress, and hypoxic processes to promote vascular dysfunction (Szasz et al, 2013).

Hypertension. Hypertension is an independent risk factor for ED (Feldman et al, 1994; Johannes et al, 2000), and its consequent cardiovascular complications such as ischemic heart disease and renal failure are associated with even higher ED prevalence (Feldman et al, 1994; Kaufman et al, 1994; Johannes et al, 2000). However, in hypertension, the increased blood pressure itself does not impair erectile function; rather, the associated arterial biochemical and structural changes are thought to be the causes (Hsieh et al, 1989; Behr-Roussel et al, 2005). In two analyses including more than 270,000 men with ED from a U.S. care claim database, the prevalence of hypertension in men with versus without ED was 41.2% versus 19.2%, respectively (Seftel et al, 2004; Sun and Swindle, 2005).

The potential determinants for ED in hypertensive men include older age, longer duration of disease, greater severity of hypertension, and the use of antihypertensive medications (Dumas et al, 2006). Arterial hypertension is characterized by altered vascular tone and increased vascular contractility resulting in high blood pressure. It is accompanied by proliferation, migration of vascular smooth muscle cells, and varying levels of inflammation of the arterial wall. The Rho-kinase pathway plays a crucial role in the regulation of arterial blood pressure (Nunes et al, 2010).

Endothelial dysfunction, oxidative stress, and autoimmune diseases are also potential causes of arterial disease and ED. The Toll-like receptor activation on cells of the vasculature in response to the release of damage-associated molecular patterns and the consequences of this activation on inflammation, vasoreactivity, and vascular remodeling has been proposed as a novel link between inflammation and hypertension (McCarthy et al, 2014). In addition, endoplasmic reticulum stress leading to endothelium-dependent contractile responses in aorta has been proposed as a cause of hypertension in a spontaneously hypertensive rat (SHR) model (Spitler et al, 2013). Increased activity of angiotensin II-mediated reduced nicotinamide adenine dinucleotide phosphate oxidase in hypertensive rats is suggested to be the cause of increased superoxide anions (Jin et al, 2008).

Mechanism of Vascular Erectile Dysfunction

Structural Changes. In arteriogenic ED, oxygen tension in corpus cavernosum blood is less than that in psychogenic ED (Tarhan et al, 1997). Formation of PGE₁ and PGE₂ is oxygen dependent, and in rabbit and human corpus cavernosum, increased oxygen tension was associated with elevation of PGE₂ and suppression of TGF- β 1-induced collagen synthesis (Moreland et al, 1995; Nehra et al, 1999). A decrease in oxygen tension may diminish cavernous trabecular smooth muscle content and lead to diffuse venous leakage (Saenz de Tejada et al, 1991b; Nehra et al, 1998).

A narrowed lumen or increased wall/lumen ratio in the arteries contributes to increased peripheral vascular resistance in hypertension. Increased resistance has also been found in the penile vasculature of SHR—an alteration ascribed to structural changes of the arterial and erectile tissue (Gradin et al, 2006; Arribas et al, 2008). Mitochondrial damage (in smooth muscle and endothelial cells) and nerve degeneration have been described in SHR (Jiang et al, 2005). Partial success in the prevention or reversal of the structural changes has been described when rats were treated with a type 1 angiotensin II receptor (AT1) blocker; an AT1 blocker with a PDE5 inhibitor; and a selective β_1 blocker, nebivolol (Mazza et al, 2006; Toblli et al, 2006a, 2006b).

Enhanced Smooth Muscle Contraction and Vasoconstriction. In animal models, increased RhoA/Rho-kinase activity leading to increased contractility of the corporeal smooth muscle is proposed to contribute to ED in diabetes (Bivalacqua et al, 2004), hypercholesterolemia (Morikage et al, 2006), hypertension (Fibbi et al, 2008), hypogonadism (Vignozzi et al, 2007), and aging (Jin et al, 2006; Andersson, 2011). Park and coworkers (2006) found that the Rho/Rho-kinase pathway is substantially involved in the development of ED and pelvic atherosclerosis, both of which could be prevented by long-term treatment with fasudil, a Rho-kinase inhibitor.

Endothelin-1 levels are elevated in plasma of men with atherosclerosis, hypertension, and hypercholesterolemia. Men with organic ED have higher venous and cavernous blood levels of endothelin-1 as well (Nohria et al, 2003; El Melegry et al, 2005). Despite this, a pilot study using an endothelin-A receptor antagonist as a treatment for men with ED did not produce positive results (Kim et al, 2002). AT1 receptor antagonist and angiotensin-converting enzyme (ACE) inhibitor have shown promise in the treatment of men with ED and hypertension and men with ED and atherosclerosis, respectively (Speel et al, 2005; Baumhäkel et al, 2008).

Impaired Endothelium-Dependent Smooth Muscle Relaxation. Endothelial dysfunction has been proposed as the common link between cardiovascular disease and ED (Brunner et al, 2005). Impairment of endothelium-dependent flow-mediated dilation of the brachial artery has been reported in men with ED, and the degree of impairment correlates with the severity of ED (Kovacs et al, 2008). A plethysmography device designed to assess endothelium-dependent vasodilation of the penis did not find a correlation between brachial and penile arteries in men with ED (Vardi et al, 2009).

Endothelial progenitor cells are regenerative cells produced in bone marrow that migrate to peripheral vessels to repair endothelial defects. The number of endothelial progenitor cells is reduced in

TABLE 26-10 Vascular and Structural Changes Leading to Erectile Dysfunction

PENILE STRUCTURE	CHANGES IN ERECTILE DYSFUNCTION
Cavernous artery	Increased vascular resistance, narrow lumen
Smooth muscle	Increased tone (hypertonicity) Decreases muscle content Alteration of potassium channels and gap junctions
Erectile tissue	Fibrosis Impaired veno-occlusive mechanism
Endothelium	Impaired endothelium-dependent relaxation
Tunica albuginea	Alteration of elastic and collagen fibers
Neurotransmitters	Decreased nNOS, eNOS

eNOS, endothelial nitric oxide synthase; nNOS, neuronal nitric oxide synthase.

men with ED and coronary heart disease and in overweight men (Foresta et al, 2005; Baumhäkel et al, 2006; Esposito et al, 2009). Short-term and long-term administration of PDE5 inhibitors increases the number of circulating endothelial progenitor cells and improves endothelial and erectile function (Foresta et al, 2005, 2009).

In SHR, the relaxing effect of acetylcholine is blunted in corporeal strips (Behr-Roussel et al, 2003). Impairment of endothelium-dependent relaxation in arteries from SHR could be ascribed to angiotensin II (Rajagopalan et al, 1996), thromboxane, and superoxide (Cosentino et al, 1998) or to high blood pressure per se (Paniagua et al, 2000) (Table 26-10).

Cavernous (Venogenic)

Failure of adequate venous occlusion has been proposed as one of the most common causes of vasculogenic impotence (Rajfer et al, 1988). Veno-occlusive dysfunction may result from various pathophysiologic processes, including degenerative tunical changes, fibroelastic structural alterations, insufficient trabecular smooth muscle relaxation, and venous shunts.

Degenerative changes (e.g., Peyronie disease, old age, and diabetes) or traumatic injury to the tunica albuginea (e.g., penile fracture) can impair the compression of the subtunical and emissary veins (Gonzalez-Cadavid, 2009). In Peyronie disease, the inelastic tunica albuginea may prevent the emissary veins from closing (Metz et al, 1983). Chiang and colleagues (1992) postulated that a decrease in the elastic fibers of the tunica albuginea and an alteration in the tunica albuginea microarchitecture may contribute to impotence in some men. Changes in the subtunical areolar layer may impair the veno-occlusive mechanism, as is occasionally seen in patients after surgery for Peyronie disease (Dalkin and Carter, 1991).

Structural alterations in the fibroelastic components of the trabeculae, cavernous smooth muscle, and endothelium may result in venous leakage. Insufficient trabecular smooth muscle relaxation, causing inadequate sinusoidal expansion and insufficient compression of the subtunical venules, may occur in anxious individuals with excessive adrenergic tone or in patients with inadequate neurotransmitter release. It has been shown that alteration of an α adrenoceptor or a decrease in NO release may heighten smooth muscle tone and impair relaxation in response to endogenous muscle relaxant (Christ et al, 1990).

Acquired venous shunts—the result of operative correction of priapism—may cause persistent glans/cavernosum or cavernosum/spongiosum shunting.

Fibroelastic Component. Loss of compliance of the penile sinusoids associated with increased deposition of collagen and decreased elastic fiber may be seen in diabetes, hypercholesterolemia, vascular disease, penile injury, or old age. Sattar and colleagues (1994) reported significant differences in the mean percentage of penile elastic fibers: 9% in normal men, 5.1% in patients with venous leakage, and 4.3% in patients with arterial disease. In an animal model of vasculogenic ED, Nehra and colleagues (1998) demonstrated that cavernous expandability correlates with smooth muscle content and may be used to predict trabecular histology. Moreland and colleagues (1995) showed that PGE₁ suppresses collagen synthesis by TGF- β 1 in human cavernous smooth muscle, which implies that intracavernous injection of PGE₁ may be beneficial in preventing intracavernous fibrosis.

Smooth Muscle. Because corporeal smooth muscle controls the vascular events leading to erection, a change in smooth muscle content and ultrastructure can be expected to affect erectile response. In a study of human penile tissue, Sattar and colleagues (1996) demonstrated a significant difference between the mean percentage of cavernous smooth muscle in normal potent men, stained with antidesmin (38.5%) or antiactin (45.2%), and that in a venogenic group (antidesmin, 27.4%; antiactin, 34.2%) or an arteriogenic group (antidesmin, 23.7%; antiactin, 28.9%). An in vitro biochemical study showed impaired neurogenic and endothelium-related relaxation of penile smooth muscle in impotent diabetic men (Saenz de Tejada et al, 1989a). In vasculogenic and neurogenic ED, the damaged smooth muscle can be a key factor, aggravating the primary cause (Mersdorf et al, 1991). Pickard and colleagues (1994) also showed impairment of nerve-evoked relaxation and α -adrenergic-stimulated contraction of cavernous muscle and reduced muscle content in men with venous or mixed venous/arterial impotence.

Ion channels are intimately involved in the biochemical events of muscle function. Fan and colleagues (1995) reported an alteration of the maxi-K⁺ channel in cells from impotent patients and suggested that this might contribute to decreased hyperpolarizing ability, altered calcium homeostasis, and impaired smooth muscle relaxation. In animal studies, Jünemann and colleagues (1991) showed significant smooth muscle degeneration with loss of cell-to-cell contact in rabbits fed a high-cholesterol diet for 3 months. In a rabbit model of vasculogenic impotence, Azadzoi and colleagues (1997) demonstrated that veno-occlusive dysfunction could be induced by cavernous ischemia. Cavernous nerve injury may also affect cavernous smooth muscle relaxation, as demonstrated in neurotomized dogs (Paick et al, 1991).

Gap Junctions. Gap junctions, intercellular communication channels, are responsible for synchronization and coordination of the erectile response (Christ et al, 1991). In severe arterial disease, the presence of collagen fibers between cell membranes reduces or abolishes their contact (Persson et al, 1989). Suadicani and colleagues (2009) reported a significant decrease of gap junction protein connexin 43 in the corpus cavernosum in aged and streptozotocin-induced diabetic rats.

Endothelium. It is now recognized that the endothelium is an important source of not only NO but also many other signaling molecules, including EDHF, PGI₂, and hydrogen peroxide. In addition, the endothelium, via transferred chemical mediators, such as NO and PGI₂, and/or low-resistance electrical coupling through myoendothelial gap junctions, modulates flow-mediated vasodilation and influences mitogenic activity, platelet aggregation, and neutrophil adhesion. Disruption of endothelial function is an early indicator of the development of vascular disease (Triggle et al, 2012). Diabetes and hypercholesterolemia have been shown to alter the function of endothelium-mediated relaxation of the cavernous muscle (Azadzoi et al, 1991) and impair erection. In a study of cell junction proteins in hypercholesterolemic mice, Ryu and colleagues (2013) reported downregulation of endothelium-specific cell-to-cell junction proteins, including claudin-5, vascular endothelial-cadherin, and platelet endothelial cell adhesion molecule 1, as well as decreased endothelial content, which may contribute to ED in these mice.

Maintenance of Structural Integrity. SHH is one of three proteins in the mammalian hedgehog family, the others being desert hedgehog and Indian hedgehog. SHH plays a key role in regulating vertebrate organogenesis, such as in the growth of digits on limbs and organization of the brain. SHH is also important in adults. It controls cell division of adult stem cells and has been implicated in development of some cancers. SHH has been shown to regulate cavernous smooth muscle apoptosis in response to signals from cavernous nerve. In an animal model of neurogenic ED, SHH protein treatment of the penis prevents cavernous nerve injury-induced apoptosis and structural changes (Podlasek, 2009).

Markers of Erectile Function. Variable coding sequence protein A1 (Vcsa1) has been proposed as a marker of erectile function in rats. Vcsa1 is downregulated in animal models of neurogenic, diabetic, and aging-associated ED. The Vcsa protein product sialorphin is an endogenous neutral endopeptidase inhibitor. In humans, there are at least three homologues to the Vcsa1 gene (hSMR3A, hSMR3B, and PROL1). Downregulation of hSMR3A has been reported in men with ED (Davies and Melman, 2008).

Various cardiovascular risk factors have been associated with the onset and the severity of ED, including markers of endothelial function, thrombosis, and dyslipidemia. These markers can be used as a cardiometabolic risk profile in patients with ED. Although NO, ADMA, and endothelin and genetic polymorphisms hold some promise as biochemical markers of cardiovascular disease and ED, these are still in development (Lippi et al, 2012).

Drug-Induced

ED is common among older men and inevitably coexists with other conditions that are themselves risk factors for ED, such as depression, diabetes, and cardiovascular disease (Feldman et al, 1994). In addition, sexual symptoms related to medication can involve a combination of complaints concerning desire, arousal, and orgasm rather than being limited to impaired function. Self-reported and questionnaire data concerning ED as a side effect of medication should be interpreted with caution.

Antihypertensive Agents. Almost all antihypertensive drugs have ED listed as a potential side effect. Nevertheless, more recent well-designed controlled clinical trials have clarified some myths.

Diuretics. Thiazide diuretics are carbonic anhydrase inhibitors that alkalinize cells and cause vasodilation. The predominant activity of thiazide diuretics is to inhibit a directly coupled Na-Cl cotransporter along the distal convoluted tubule of the kidney. Acutely, when extracellular fluid volume depletion occurs because of salt wasting, cardiac output tends to decline, resulting in reactive vasoconstriction. However, on a long-term basis, cardiac output is regulated according to metabolic needs, and vasodilation supervenes, returning cardiac output toward baseline; this transforms hypotension from hypovolemic to vasodilatory (Ellison et al, 2009).

This class of drug has been extensively studied. Data from a large trial in the United Kingdom showed that twice as many men taking thiazides for mild hypertension reported ED than men taking propranolol or placebo—the most common reason for withdrawal from the bendrofluazide arm of the study (“Adverse reactions to bendrofluazide and propranolol for the treatment of mild hypertension,” 1981).

Similar findings were documented from the Treatment of Mild Hypertension Study (TOMHS), where the prevalence of ED at 2 years in men taking low-dose thiazide was twice that of men taking placebo or alternative agents (Grimm et al, 1997). After 4 years of treatment, the prevalence of ED in the placebo group approached that of the thiazide group, a finding not fully explained by dropouts. It may be that thiazide therapy, rather than causing ED directly, unmasks it at an earlier stage. A study comparing sexual side effects of thiazide, placebo, or atenolol in hypertensive patients also found a higher rate of ED in the thiazide group, although this was ameliorated by weight loss (Wassertheil-Smoller et al, 1991). The mechanism of diuretic-induced ED remains to be elucidated.

β -Adrenergic Blockers. Receptor studies show that only 10% of adrenoceptors in the penile tissue are of the β type, and their

stimulation is thought to mediate relaxation (Andersson and Wagner, 1995). This response is attenuated *in vitro* by nonselective drugs such as propranolol, possibly via a prejunctional β_2 -receptor effect (Srilatha et al, 1999), but not by cardiac-selective agents such as practolol. β antagonists also exert an inhibitory effect within the CNS, perhaps leading to decreased sex hormone levels (Suzuki et al, 1988).

The differential effects of β -adrenoceptor antagonists on erectile function may be explained by whether they are general antagonists, are selective antagonists, or possess vasodilatory properties. Non-selective drugs such as propranolol are associated with higher prevalence of ED compared with prevalence of ED observed in patients treated with placebo or ACE inhibitors (Croog et al, 1986). Subsequent trials using agents with higher selectivity for the β_1 adrenoceptor such as acebutolol have shown a substantial reduction in ED with no difference between placebo and ACE inhibitor groups (Grimm et al, 1997). Carvedilol, a general β -adrenoceptor antagonist that also causes vasodilation by blocking α_1 adrenoceptors, has been associated with worsening sexual function (Fogari et al, 2001). Some more recently introduced β_1 -adrenoceptor antagonists, such as nebivolol, have vasodilatory effects mediated by release of NO (Reidenbach et al, 2007). In crossover studies using nebivolol versus the selective β_1 -adrenoceptor antagonists metoprolol and atenolol, nebivolol did not decrease sexual intercourse activity in hypertensive men and in some cases had positive effects on erectile function (Boydak et al, 2005; Brixius et al, 2007).

α -Adrenoceptor Blockers. Animal studies have demonstrated a positive effect on erection for α antagonists, particularly antagonists acting on the α_1 receptor, by increasing or prolonging the relaxant response of cavernous smooth muscle (Andersson and Wagner, 1995). In addition, prejunctional α_2 receptor activation modulates the release of noradrenaline, suggesting a putative relaxant role for α_2 blockers. In clinical observations, drugs such as doxazosin, used to treat hypertension (Grimm et al, 1997) or reduce urinary tract symptoms (Flack, 2002), were not associated with complaints of ED and had lower rates than in placebo groups. Drugs stimulatory to the α_2 receptor, such as clonidine, result in diminished erectile function clinically and experimentally by peripheral and central mechanisms (Srilatha et al, 1999). Methyldopa, a centrally acting drug, has also been associated with ED in controlled trials comparing it with placebo and other antihypertensive agents (Croog et al, 1988), and it may act by antagonizing hypothalamic α_2 adrenoceptors.

Angiotensin-Converting Enzyme Inhibitors. ACE inhibitors lack any easily appreciated peripheral or central effect that would interfere with sexual function. An *in vivo* experiment showed that the ACE inhibitor captopril did not cause any significant adverse effect on sexual function in awake normotensive rats (Srilatha et al, 1999). In three clinical studies of hypertensive patients comparing an ACE inhibitor with other agents and placebo, all found either no difference from placebo or improved sexual function over baseline compared with other agents (Croog et al, 1988; Suzuki et al, 1988; Grimm et al, 1997).

Angiotensin II Type 1 Receptor Antagonist. In studies of hypertensive or aging normotensive animals, the AT1 receptor antagonists (e.g., losartan, valsartan, candesartan) reverse structural changes in the penile vasculature and appear to conserve erectile function (Hale et al, 2001, 2002; Park et al, 2005; Hannan et al, 2006). In clinical cross-sectional studies, AT1 receptor antagonists, in contrast to other antihypertensive drugs, seem to improve erectile function (Doulmas et al, 2006). In a crossover study comparing valsartan with the β -adrenoceptor antagonist carvedilol, valsartan had a beneficial effect on preexisting sexual dysfunction and had no adverse sexual effects during 12 months of treatment (Fogari et al, 2001). Treatment with losartan for 3 months has also been reported to improve sexual function (Llisterri et al, 2001).

Calcium Channel Blockers. Clinical studies of calcium channel blockers have demonstrated no adverse effect on erection; ejaculatory complaints, which may be due to decreased force of bulbocavernosus muscles, seem short-lived (Suzuki et al, 1988). In

the TOMHS study, there was no increase in ED in the amlodipine group compared with placebo (Grimm et al, 1997). Another study also showed no increase in the prevalence of ED when hypertension was treated with diltiazem alone or in combination with an ACE inhibitor (Cushman et al, 1998).

Aldosterone Receptor Antagonist. Spironolactone and eplerenone are mineralocorticoid-blocking agents used for their ability to block the epithelial and nonepithelial actions of aldosterone. Spironolactone is a nonselective mineralocorticoid receptor antagonist with moderate affinity for progesterone and androgen receptors. The latter property increases the likelihood of endocrine side effects, including loss of libido, gynecomastia, and impotence. Eplerenone is a next-generation aldosterone receptor antagonist selective for aldosterone receptors alone. It has less affinity for progesterone and androgen receptors (Sica, 2005).

Summary. Treatment of mild to moderate hypertension requires agents with an acceptable side-effect profile to minimize noncompliance. Thiazide diuretics are associated with higher rates of ED, although this may be reduced by combination therapy and weight loss. α_1 -Blockers and angiotensin II receptor blockers tend to improve sexual functioning during treatment and may be useful when starting antihypertensive therapy in men with preexisting ED (Khan et al, 2002) (Table 26-11).

Psychotropic Medication. As with hypertension, the underlying disorder may be more relevant for ED than the medication. However, receptor complexity and interrelationship of pathways within the CNS make it extremely likely that neurons and ganglia involved in sexual functioning will be affected by psychotropic drugs, leading to functional changes that may be positive or negative. An example is the loss of sexual desire among nonmedicated patients with schizophrenia, whereas patients on antipsychotic drugs have shown greater desire but increased erectile and ejaculatory disturbance (Aizenberg et al, 1995).

Antipsychotics. Members of this class of drug have many effects on CNS receptors and may act peripherally. The therapeutic effect of antipsychotics is thought to relate to dopaminergic receptor blockade within the limbic and prefrontal areas of the brain. Their

unwanted effects are due to β -adrenergic blockade and anticholinergic properties and to antidopaminergic actions within the basal ganglia, causing extrapyramidal side effects that commonly produce sexual symptoms (Sullivan and Lukoff, 1990).

The occurrence of extrapyramidal effects differentiates older "typical" antipsychotics (frequent extrapyramidal effects) from newer "atypical" antipsychotics (less common extrapyramidal effects). This difference probably relates to differential affinities for particular classes of receptor (Strange, 2001) or avidity for particular areas of the cerebral cortex (Westerink, 2002). An additional effect of dopamine blockade, hyperprolactinemia, which also alters sexual function by reducing dopamine release in permissive cerebral centers, is more common with older "typical" agents (Smith and Talbert, 1986).

Animal experiments, chiefly in rats, show that D1 receptor activation in the MPOA of the hypothalamus facilitates erection through intermediary oxytocinergic and spinal cholinergic pathways. It is also possible that activation of D2 receptors in this area has the opposite effect (Zarrindast et al, 1992). Older agents such as haloperidol and flupenthixol have been shown to reduce apomorphine-induced erections in experimental animals by means of D1 receptor antagonism (Andersson and Wagner, 1995). In addition, systemic administration of antipsychotic agents in rabbits produced erection by a local nondopaminergic action, possibly involving antagonism of α_1 adrenoceptors (Naganuma et al, 1993). The clinical effect of antipsychotics on sexual function varies according to their affinity for particular receptors.

In a nonrandomized comparative study of antipsychotic medications, the prevalence of sexual dysfunction ranged from 40% to 70% (Wirshing et al, 2002). Newer agents such as clozapine showed a lower reduction in sexual desire, and the group taking risperidone had the greatest decrease in erectile frequency.

Antidepressants. Sexual side effects of antidepressants in men and women are varied but are important factors governing compliance because these drugs are commonly prescribed to younger and middle-aged adults. In a Cochrane review of 15 randomized trials, besides changing medications, addition of bupropion or a PDE5 inhibitor to an antidepressant seems to be an effective method to correct antidepressant-associated ED (Rudkin et al, 2004).

Tricyclics act by inhibiting the reuptake of catecholamines in the CNS. Their sexual side-effect profile is thought to relate to peripheral anticholinergic and β -adrenergic effects. It is also possible that they antagonize 5-HT receptors. Controlled clinical studies suggest that orgasmic disorders in both sexes are frequent, explaining the use of these drugs as inhibitors of ejaculation (Harrison et al, 1986; Monteiro et al, 1987).

Monoamine oxidase inhibitors are associated with higher rates of orgasmic dysfunction in controlled trials (Harrison et al, 1986), but the nature of the central or peripheral mechanisms involved is uncertain.

Selective serotonin reuptake inhibitors (SSRIs) are the class of drug commonly used to treat depression at the present time. They inhibit the reuptake of 5-HT into CNS neurons and can produce stimulatory effects on various 5-HT receptors. It is estimated that up to 50% of patients taking SSRIs experience a change in sexual function (Rosen et al, 1999; Keltner et al, 2002). Possible mechanisms include stimulation of 5-HT₂ and 5-HT₃ receptors, which may inhibit erectogenic pathways within the spinal cord (Tang et al, 1998); decreased dopamine release in the MPOA (Maeda et al, 1994); inhibition of NOS; and lower serum levels of luteinizing hormone, follicle-stimulating hormone, and testosterone (Safarinejad, 2008). A controlled clinical study suggested that the improvement in sexual function resulting from alleviation of clinical depression with use of SSRIs outweighed any negative effect (Michelson et al, 2001). However, other placebo-controlled randomized studies revealed increased sexual dysfunction, mainly anorgasmia, in the group treated with SSRIs (Labbate et al, 1998; Croft et al, 1999). Further studies have suggested that these adverse effects can be modified by cotreatment with other drugs such as sildenafil (Fava et al, 2006) or mianserin (Aizenberg et al, 1997).

SSRIs differ in their ability to cause ED. A high incidence has been observed in patients treated with paroxetine (Kennedy et al,

TABLE 26-11 Effect of Antihypertensive Agents on Sexual Function

AGENT	EFFECT	MECHANISM
Diuretics	ED (twice as common as placebo)	Unknown
β -Blocker (nonselective)	ED	Prejunctional α_2 -receptor inhibition
β_1 -Blocker (selective)	None	
α_1 -Blocker	Decreases ED rate but may cause retrograde ejaculation	Failure of sympathetically induced closure of internal sphincter and proximal urethra during ejaculation
α_2 -Blocker	ED	Inhibition of central α_2 receptor
Angiotensin-converting enzyme inhibitor	None	
Angiotensin II receptor blocker	Decreases ED rate	
Calcium channel blocker	None	

ED, erectile dysfunction.

2000), whereas a lesser impact has been reported with citalopram (Mendels et al, 1999). This difference suggests that mechanisms other than inhibition of serotonin reuptake may be involved, which is supported by a report that short-term or long-term administration of paroxetine, but not citalopram, caused ED in rats by inhibiting NO production (Angulo et al, 2001b). The inhibitory effects induced by short-term administration of paroxetine on erectile function in the rat can be prevented by inhibition of PDE5 with vardenafil (Angulo et al, 2003a).

Other Antidepressants. Animal experiments suggest that stimulation of 5-HT₁ receptors within the CNS modulates sexual function, with the 5-HT_{1A} subtype increasing ejaculation and the 5-HT_{1C} subtype improving erection. Recently developed antidepressants such as mirtazapine and nefazodone tend to have beneficial effects on sexual function, possibly by activating the 5-HT_{1C} receptor, which augments sexual response (Stancampiano et al, 1994), although they may also antagonize the 5-HT_{2C} receptor (Millan et al, 2000). The isolated reports of priapism seen with a prototype agent, trazodone, may be related to the 5-HT_{1C} erectogenic effect seen with its primary metabolite, *m*-chlorophenylpiperazine, in experimental animals (Andersson and Wagner, 1995). In a clinical study, trazodone was shown to increase nocturnal erectile activity, despite reducing REM sleep (Ware et al, 1994).

Anxiolytics. Although not previously associated with ED, anxiolytics have been implicated in sexual problems by the MMAS study (Derby et al, 2001). Benzodiazepines are thought to potentiate the action of GABA in the reticular and limbic system, but they may also affect the serotonin and dopaminergic pathways. Experimental studies suggest that GABAergic drugs inhibit erection induced by apomorphine, a dopamine agonist (Zarrindast and Farahvash, 1994). A controlled clinical study demonstrated that a combination of lithium and benzodiazepine was associated with a significantly higher rate of sexual dysfunction than treatment with lithium alone (Ghadirian et al, 1992). More recent anxiolytic agents, such as bupropion, acting mainly by inhibiting dopamine reuptake, and buspirone, acting on 5-HT_{1A} receptors, were not associated with sexual side effects in placebo-controlled trials (Coleman et al, 2001) and can be used to alleviate sexual symptoms caused by other antidepressant medication (Gitlin et al, 2002).

Anticonvulsants. Epileptic discharges may affect the function of the hypothalamic-pituitary axis and the level of hormones important for sexual function (Morris and Vanderkolk, 2005). Sexual function, bioavailable testosterone levels, and gonadal efficiency in men with epilepsy who take lamotrigine are comparable to control and untreated values and significantly greater than in men treated with carbamazepine or phenytoin (Herzog et al, 2004). Orgasmic dysfunction is common in patients who receive carbamazepine therapy, and loss of sexual desire is common in men treated with valproate (Kuba et al, 2006). There are reports of improved sexual function and hypersexuality in patients treated with lamotrigine (Gil-Nagel et al, 2006; Grabowska-Grzyb et al, 2006).

Antiandrogens

Androgens are believed to modify sexual behavior by modulating androgen receptors within the CNS. **Antiandrogens cause partial or near-complete blockade of androgen's action by inhibiting production of or antagonizing the androgen receptor.** The effects of androgen deficiency on sexual activity are variable, ranging from complete loss to normal function. Experimental studies in humans suggest that nocturnal erections during REM sleep are androgen dependent, whereas erections in response to visual sexual stimulation are independent (Andersson and Wagner, 1995). An additional peripheral effect has been suggested from animal experiments in which castration decreased NOS activity within the rat corpus cavernosum, leading to reduced erectile activity. Testosterone restored NOS activity, but treatment with finasteride prevented this recovery, suggesting that DHT may be the important androgen in penile tissue (Lugg et al, 1995).

The 5 α -reductase inhibitors, finasteride and dutasteride, are the antiandrogens with the least effect on circulating

testosterone. In randomized placebo-controlled studies of patients given finasteride (5 mg daily) for prostatic symptoms, approximately 5% complained of decreased desire and ED compared with 1% in the placebo group (Gormley et al, 1992). At the lower dose used to treat male-pattern alopecia (1 mg daily), no sexual dysfunction was seen (Tosti et al, 2001). However, persistent sexual dysfunction for months to years after discontinuation of finasteride for hair loss (Propecia; 1 mg) has been reported. The side effects include low libido, ED, decreased arousal, and difficulty with orgasm (Irwig and Kolukula, 2011).

More complete androgen ablation is achieved by competitive antagonism at the androgen receptor, preventing signal transduction of testosterone and DHT. Nonsteroidal drugs such as flutamide and bicalutamide have relatively pure effects on the androgen receptor. The steroidal antiandrogen cyproterone acetate also has inhibitory effects on the hypothalamus. These drugs are used in the palliative treatment of locally advanced and metastatic prostate cancer, either alone or in combination with a luteinizing hormone-releasing hormone (LHRH) agonist or antagonist. When used alone, nonsteroidal antiandrogens are associated with an increase in serum testosterone levels. When nonsteroidal antiandrogen is combined with an LHRH agonist or antagonist, the combination reduces testosterone to the castrate range. The main side effect is a reduction of sexual desire, which occurs in up to 70% (Iversen et al, 2001).

In a clinical trial with larger sample size and longer duration, treatment with bicalutamide alone resulted in a smaller decrease in sexual desire than did castration (Iversen et al, 2000). However, in another large controlled trial, treatment with either flutamide or cyproterone resulted in a gradual loss of sexual desire over 2 to 6 years in approximately 80% (Schroder et al, 2000). In a placebo-controlled study, half of patients receiving bicalutamide therapy experienced loss of erectile function, even at a low dose of 50 mg (Eri and Tveter, 1994).

The near-complete androgen deprivation achieved by medical castration with LHRH antagonist (immediate testosterone suppression) or agonists (with an initial surge of testosterone) results in a profound loss of sexual desire, which is usually accompanied by ED (Basaria et al, 2002). In a small study, nocturnal penile tumescence (NPT) monitoring before and after initiation of therapy provided objective confirmation (Marumo et al, 1999).

Miscellaneous Drugs

Many other drugs are suggested to have sexual side effects, in particular, ED in men, but these contentions are usually based on anecdotal case reports or postmarketing drug alerts rather than controlled trials.

Digoxin. In an experimental in vitro study with isolated human corpus cavernosum tissue, digoxin attenuated the relaxant response to acetylcholine and intrinsic nerve stimulation; this was linked to findings of reduced penile rigidity not seen in men given a placebo after visual sexual stimulation (Gupta et al, 1998). A randomized clinical study confirmed a negative effect on general sexual functioning linked to a decrease in plasma testosterone (Neri et al, 1987). However, other investigators did not find change in sex and adrenal hormone levels in men taking digitalis (Kley et al, 1984).

Statins. Statins are used to reduce lipid levels and are commonly used in men likely to have established risk factors for sexual dysfunction, particularly ED. In a single placebo-controlled trial, the rate of ED was twice as high (12% vs. 6%) in men taking a statin, despite improvement in other parameters of hyperlipidemic endothelial dysfunction (Bruckert et al, 1996). In another study of 93 men attending cardiovascular risk clinics, after 6 months of statin therapy, the mean IIEF scores were reduced from 21 to 6.5 (range 0 to 25; $P < .001$), and 22% experienced new-onset ED. The authors suggest that ED after statin therapy is more likely in patients with severe endothelial dysfunction secondary to established cardiovascular risk factors including age, smoking, and diabetes (Solomon et al, 2006). In contrast, in the large Scandinavian simvastatin survival study, 4444 patients with coronary arterial disease were randomly assigned to treatment with simvastatin or placebo for up to

6 years. ED was found in 28 placebo-treated patients (8 resolved) and in 37 simvastatin-treated patients (14 resolved) (Pedersen and Faergeman, 1999). The underlying disease process appears to be the cause of ED in men treated with statins rather than the drug itself.

Regarding sexual side effects, the most studied statin is atorvastatin. In clinical studies, atorvastatin has been reported to have the following positive effects: (1) improvement in nocturnal penile activity and mean scores on the Sexual Health Inventory in Men questionnaire from 14.2 to 20.7 in hyperlipidemic patients treated for 4 months (Saltzman et al, 2004); (2) when combined with the ACE inhibitor quinapril, positive effects on ED in men with established penile disease and suboptimal response to PDE inhibitors (Bank et al, 2006); (3) improvement in the response to sildenafil in men with ED not initially responsive to sildenafil (Herrmann et al, 2006); (4) when combined with sildenafil, improvement in erectile function recovery in men who had undergone bilateral nerve-sparing radical prostatectomy (Hong et al, 2007); and (5) positive effect on IIEF questionnaire scores in patients with hyperlipidemia followed for 12 months (Dogru et al, 2008).

Statins are classified as natural (lovastatin), semisynthetic (simvastatin), and synthetic (atorvastatin, cerivastatin) and are structurally heterogeneous. The statins may have different effects on sexual function, which remain to be elucidated.

Histamine H₂ Receptor Antagonists. Cimetidine and ranitidine were widely prescribed for prophylaxis and treatment of peptic ulcer disease. Case reports suggested that cimetidine was associated with ED. A single in vitro animal study suggested that H₂ receptor stimulation causes cavernous relaxation, possibly via endothelial release of NO (Andersson and Wagner, 1995).

Opiates. Long-term intrathecal administration of opiates results in hypogonadotropic hypogonadism and associated sexual dysfunction that can be restored with appropriate supplementation (Abs et al, 2000). However, administration of opioid antagonists to older men with ED was not found to improve erectile function measured objectively by NPT monitoring (Billington et al, 1990). Opioids have a generalized depressant effect on sexual function when directly administered to the MPOA in rat brain, but treatment with the opioid receptor antagonist naloxone had no sexual effect on healthy male volunteers (Andersson and Wagner, 1995).

Antiretroviral Agents. Hypogonadism and ED appear to be more common among men infected with human immunodeficiency virus (HIV) compared with age-matched men in the general U.S. population (Crum et al, 2005). Sexual dysfunction seems to be a common event after the introduction of antiretroviral therapy. The average prevalence is ED, 46%; decreased libido, 44%; ejaculatory disturbances, 39%; and orgasmic disorders, 27% (Collazos, 2007). These disturbances seemed to be more common in patients treated with protease inhibitors. Because these patients may have diseases involving several organ systems and may be taking multiple drugs, the precise mechanism is difficult to determine.

Tobacco. Cigarette smoking may induce vasoconstriction and penile venous leakage because of its contractile effect on the cavernous smooth muscle (Juenemann et al, 1987a). In an NPT study in cigarette smokers, Hirshkowitz and colleagues (1992) reported an inverse correlation between nocturnal erection (rigidity and duration) and the number of cigarettes smoked per day: Men who smoked more than 40 cigarettes had the weakest and shortest nocturnal erections. The Boston Area Community Health (BACH) survey used a multistage stratified random sample to recruit 2301 men, 30 to 79 years to, from Boston. The authors' report indicates a dose-response association between smoking and ED with a statistically significant effect observed with 20 or more pack-years of exposure. Passive smoking is associated with a small, statistically insignificant increase in risk of ED comparable to approximately 10 to 19 pack-years of active smoking (Kupelian et al, 2007). In an experiment to elucidate the mechanisms of ED associated with tobacco use, nicotine-free and tar-free cigarette smoke extract was injected subcutaneously into adult male rabbits once a day for 5 weeks. The authors reported impaired NO production from blunted NOS activity, downregulation of nNOS protein,

accumulation of endogenous NOS inhibitors, enhanced arginase activity, and upregulation of arginase I protein in cavernous tissue. Cigarette smoke extract also caused accumulation of endogenous NOS inhibitors secondary to impaired dimethylarginine dimethylaminohydrolase activity and decreased expression of dimethylarginine dimethylaminohydrolase I protein. These alterations may be relevant to ED after administration of cigarette smoke extract (Imamura et al, 2007).

Alcohol. Alcohol in small amounts improves erection and sexual drive because of its vasodilatory effect and suppression of anxiety; however, large amounts can cause central sedation, decreased libido, and transient ED. In the Western Australia Men's Health Study, Chew and colleagues (2009) reported that compared with never-drinkers, the age-adjusted odds of ED were lower among current, weekend, and binge drinkers and higher among ex-drinkers.

Chronic alcoholism may result in liver dysfunction, decreased testosterone and increased estrogen levels, and alcoholic polyneuropathy, which may also affect penile nerves (Miller and Gold, 1988). In an in vitro study of rabbits given 5% alcohol for 6 weeks, Saito and colleagues (1994) reported augmented smooth muscle contraction and relaxation to both electrical field stimulation and vasoconstrictors such as phenylephrine and potassium chloride, but not to sodium nitroprusside, suggesting changes in neurovascular function. In a study of subacute alcohol effect, mice were exposed to alcohol vapor for 7 or 14 days. The authors reported impaired endothelium-dependent relaxation of cavernous smooth muscle and damage of endothelium in the group of mice exposed for 14 days but not the group exposed for 7 days (Aydinoglu et al, 2008) (Table 26-12).

TABLE 26-12 Drug-Induced Erectile Dysfunction and Suggested Alternatives

CLASS	KNOWN TO CAUSE ERECTILE DYSFUNCTION	SUGGESTED ALTERNATIVES
Antihypertensives	Thiazide diuretics General β blockers	α -Blockers Calcium channel blockers Specific β -blockers Angiotensin-converting enzyme inhibitors Angiotensin II receptor antagonists
Psychotropics	Antipsychotics Antidepressants Anxiolytics	Newer anxiolytics (bupropion, buspirone)
Antiandrogen	Androgen receptor antagonists Luteinizing hormone-releasing hormone agonists 5 α -Reductase inhibitors	
Opiates		
Antiretroviral agents		
Tobacco		Quit smoking
Alcohol	Large amount	Small amount

U.S. Community Survey of Prescription Drugs and Erectile Dysfunction. The BACH survey used a multistage stratified design to recruit a random sample of 2301 men 30 to 79 years old. To investigate the association of ED with commonly used medications, including antihypertensive agents, psychoactive agents, and pain and anti-inflammatory medications. ED was assessed using the IIEF-5 questionnaire. Multivariable analyses showed benzodiazepines and tricyclic antidepressants were associated with ED, whereas no association was observed for SSRIs/serotonin-norepinephrine reuptake inhibitors and atypical antipsychotics. The use of antihypertensive treatment, whether in monotherapy or in conjunction with others, and pain or anti-inflammatory medications was not associated with ED after accounting for confounding factors (Kupelian et al, 2013).

Aging, Systemic Disease, and Other Causes

Numerous studies have indicated a progressive decline in sexual function in “healthy” aging men. Masters and Johnson (1977) noted many changes in older men, including greater latency to erection, less turgidity, loss of forceful ejaculation and decreased volume, and a longer refractory period. Decreased frequency and duration of nocturnal erection with increasing age were reported in a group of men who had regular intercourse (Schiavi and Schreiner-Engel, 1988). Other research has also indicated a decrease in penile tactile sensitivity with age (Rowland et al, 1989). A heightened cavernous muscle tone may also contribute to the decreased erectile response in older men (Christ et al, 1990). In one study, a decrease in testosterone in aging impotent men in association with relatively normal gonadotropins was reported, suggestive of hypothalamic-pituitary dysfunction (Kaiser et al, 1988). Vascular endothelial dysfunction is regarded as a primary phenotypic expression of normal human aging. This senescence-induced disorder is the likely culprit underlying the increased cardiovascular and metabolic diseases associated with aging. Aging impairs endothelial function through reduced eNOS expression and action, accelerated NO degradation, increased PDE activity, inhibition of NOS activity by endogenous NOS inhibitors, increased production of reactive oxygen species, inflammatory reactions, decreased endothelial progenitor cell number and function, and impaired telomerase activity or telomere shortening (Toda, 2012).

Penile structural and functional changes have been documented in various animal studies. Costa and Venda (2008) reported progressive decline of smooth muscle content and increase in the caliber of vascular spaces in the corpus cavernosum with increasing age in Wistar rats. Suadicani and colleagues (2009) showed a significant decrease in gap junction protein connexin 43 and purinoceptor subtype P2X1R and an increase in purinoceptor subtype P2X7R in the corpus cavernosum of aging Fischer-344 rats. Ferrini and colleagues (2001a, 2001b) reported an increase of inducible NO, peroxynitrite formation, and elevation of apoptotic index in the corpus cavernosum and hypothalamic regions. The increased contractile property of the erectile tissue associated with aging may be due to elevated RhoA/Rho-kinase activity (Jin et al, 2006), enhanced renin-angiotensin system (Park et al, 2005), or impaired angiotensin-(1-7)-mediated relaxation (Yousif et al, 2007).

Diabetes Mellitus. Diabetes mellitus is a common chronic disease, affecting 0.5% to 2% of the worldwide population. The prevalence of ED is three times higher in diabetic men (28% vs. 9.6%) (Feldman et al, 1994), occurs at an earlier age, and increases with disease duration, being approximately 15% at age 30 and increasing to 55% at 60 years (McCulloch et al, 1980, 1984). ED among men with diabetes is more frequent in men with coexisting neuropathy. In a study of men presenting with ED, the authors found a twofold increase of hypogonadism in men with diabetes (24% vs. 12%) (Corona et al, 2006). The presence of ED is associated with more than 14 times higher risk for silent coronary artery disease, higher major cardiovascular morbidity, and mortality in diabetic men (Gazzaruso et al, 2004). This evidence indicates the presence of ED in diabetic patients could predict future major cardiovascular events. Diabetes mellitus may cause ED by

affecting one or a combination of the following: psychological well-being, CNS function, androgen secretion, peripheral nerve activity, endothelial cell function, and smooth muscle contractility (Dunsmuir and Holmes, 1996).

In 12% of diabetic men, deterioration of sexual function can be the first symptom. Duplex ultrasound after intracavernous injection has revealed a high prevalence (>75%) of penile arterial insufficiency among diabetic men with ED (Wang et al, 1993). Pathologic changes in the cavernous arteries (Michal, 1980), ultrastructural changes in the cavernous smooth muscle (Mersdorf et al, 1991), and impaired endothelium-dependent relaxation of the corporeal smooth muscle (Saenz de Tejada et al, 1989a) also have been noted in penile specimens from diabetic men with ED. Hirshkowitz and colleagues (1990) reported that impotent men with diabetes have fewer sleep-related erections, shorter tumescence time, diminished penile rigidity, decreased heart rate response to deep breathing, and lower penile blood pressure than age-matched nondiabetic men. Different severities of endothelial apoptosis between diabetic patients who are “responders” and “nonresponders” to sildenafil have also been reported (Condorelli et al, 2013).

Numerous type 1 and type 2 diabetic animal models have been used to study the basic mechanisms of diabetes-induced ED. In these animals, diabetes causes endothelial cell dysfunction, incompetent cavernous endothelial cell-cell junctions resulting in an increased prevalence of vascular disease (Ryu et al, 2013). Other effects include decreased nNOS, reduced activity of eNOS, oxidative stress, increased advanced glycation end products, decreased elastin, reduced VEGF, hypercontractility of cavernous erectile tissue, and decreased smooth muscle/collagen ratio leading to impairment of the veno-occlusive mechanism. Kilarkaje and associates (2013) reported that angiotensin II signaling is also involved in diabetes-induced structural changes and oxidative DNA damage in the corpus cavernosum of rats and that modulation of the signaling by captopril, losartan, and angiotensin-(1-7) restores the effects of diabetes mellitus. Activated Rho-kinase mediates diabetes-induced elevation of vascular arginase activation, and impaired corpora cavernosa relaxation has also been reported (Toque et al, 2013). Celtek and associates (2013) revisited the concept of “point of no return” in the course of diabetic ED and proposed that research focus on the role of vasa nervorum and advanced glycation end products. Summaries of mechanistic studies in humans and animal models, derived from the committee report of the Second International Consultation of Sexual Medicine (Saenz de Tejada et al, 2005), are shown in Tables 26-13 and 26-14.

Metabolic Syndrome. The metabolic syndrome includes glucose intolerance, insulin resistance, obesity, dyslipidemia, and hypertension. Higher prevalence of ED (26.7%) in men with metabolic syndrome relative to control subjects (13%) has been reported. The prevalence of ED increases as the number of metabolic syndrome components increases (Esposito et al, 2005). In an analysis of the Baltimore Longitudinal Study of Aging, in which men were followed for a mean of 5.8 years, Rodriguez and colleagues (2007) confirmed that the prevalence of metabolic syndrome increases with age and is associated with lower androgen levels. They also found that lower total testosterone levels, along with lower sex hormone-binding globulin levels, predicts a higher incidence of metabolic syndrome. Men with metabolic syndrome have an increased prevalence of ED, reduced endothelial function score, and higher circulating concentrations of C-reactive protein compared with men without metabolic disorders (Esposito et al, 2005). La Vignera and associates (2012) studied endothelial cell turnover by blood endothelial progenitor cells and endothelial microparticles and reported highest levels in men with both metabolic syndrome and arteriogenic ED, followed by men with metabolic syndrome without ED and then men without metabolic syndrome and ED. In a study of endothelial function in patients with metabolic syndrome and ED, Tomada and associates (2013) reported an imbalance of angiopoietins in patients with metabolic syndrome and ED and suggested that angiopoietins may be early markers of endothelial dysfunction in this population with higher cardiovascular risk. In insulin-resistant obese Zucker rats,

TABLE 26-13 Summary Findings of Studies in Diabetic Patients

FOCUS	FINDING
Anatomic	<ul style="list-style-type: none"> • More atheromatic lesions in large vessels and stenosis in pudendal and iliac arteries
Functional	<ul style="list-style-type: none"> • Decreased number and rigidity of nocturnal erections • Lower penile rigidity after intracavernous injection of vasodilators • High prevalence of penile arterial insufficiency studied with duplex ultrasound
CAVERNOUS TISSUE STUDIES	
Ultrastructural	<ul style="list-style-type: none"> • Decreased smooth muscle content, increased collagen, thickening of basal lamina, and loss of endothelial cells (more severe in men with diabetes)
Functional	<ul style="list-style-type: none"> • Reduced endothelial and neurogenic NO-mediated penile smooth muscle relaxation but not nitroprusside-induced relaxation (suggesting impaired NO release or synthesis) • Increased advanced glycation end products in cavernous tissue • Contractile response to α-adrenergic agonist is higher in type 1 but not type 2 diabetics • In human penile arteries, EDHF-mediated endothelium-dependent relaxation is significantly reduced in penile resistance arteries from diabetic patients • Exposure to hyperglycemia induces increased expression of collagen, decreased proliferation, and increased programmed cell death (apoptosis). Expression of tumor necrosis factor-α is also increased • Insulin is thought to enhance NOS activity by increasing transport of L-arginine into the cell and furnishing greater quantities of the essential cofactor NADPH. These effects are reversed in insulin deficiency or insulin resistance in diabetes • The inducible form (arginase II) of arginase, an enzyme that competes with NOS for the substrate L-arginine, is overexpressed in corpus cavernosum of diabetic patients, where inhibition of arginase restores NOS activity

EDHF, endothelium-derived hyperpolarizing factor; NADPH, reduced nicotinamide adenine dinucleotide phosphate; NO, nitric oxide; NOS, nitric oxide synthase.

TABLE 26-14 Summary Findings of Studies in Diabetic Animal Models

MODEL	FINDING
Streptozocin-induced diabetic rats or mice	<ul style="list-style-type: none"> • Increased activity of AC and GC, resulting in production of more cAMP and cGMP in response to PGE₁ and nitroprusside, respectively • Decreased endothelial and neurogenic NO-mediated cavernous muscle relaxation • Increased prostacyclin synthesis • Increased cavernous muscle tone owing to upregulation of ET-A receptors • Increased contractile prostaglandins and free oxygen radicals in hyperglycemic state, resulting in reduced response to acetylcholine (reversed by indomethacin and antioxidants) • Increased levels of oxygen free radicals and oxidative stress injury. Preventive treatment with an antioxidant prevented the appearance of endothelial dysfunction in cavernosal tissue, whereas restorative treatment with same antioxidant only partially reversed the impairment of endothelium-dependent relaxation • Increased glycated hemoglobin, which impairs endothelium-dependent relaxation in aorta and corpus cavernosum from diabetic rats. This effect is reversed by SOD, the scavenger of superoxide anions • Inhibition of AGE formation improves endothelium-dependent relaxation and restores erectile function in diabetic rats • Impaired responses attributable to EDHF in the vasculature of diabetic animals • Plasma concentration and vascular content of L-arginine are reduced in diabetic rats • NO-dependent selective nitrergic nerve degeneration in diabetes
Diabetic rabbit	<ul style="list-style-type: none"> • Production of cAMP in response to PGE₁ or forskolin is reduced after 6 months, but not 3 months • Increased glucose-induced production of PKC mediated by oxidative stress in rabbit corpus cavernosum smooth muscle cells • Oxidative stress interferes with endothelial function in diabetic erectile tissue. This is supported by the potentiating effect of SOD or the natural antioxidant, vitamin E, on endothelium-dependent relaxation of corpus cavernosum from rabbits

AC, adenylyl cyclase; AGE, advanced glycation end product; cAMP, cyclic adenosine monophosphate; cGMP, cyclic guanosine monophosphate; EDHF, endothelium-derived hyperpolarizing factor; ET-A, endothelin-A; GC, guanylyl cyclase; NO, nitric oxide; PGE₁, prostaglandin E₁; PKC, protein kinase C; SOD, superoxide dismutase.

Sánchez and coworkers (2012) reported uncoupling of nNOS in the dysfunctional nitric oxide vasorelaxation of penile arteries (see Fig. 26-13).

Chronic Renal Failure. Sexual dysfunction is common in men with chronic renal failure. In a survey of 69 men on hemodialysis, only 55% were sexually active, and the predominant sexual dysfunctions were loss of or diminished sexual needs (84.7%), ED (44.5%), and inhibited or lack of ejaculation (51.5%) (Lew-Starowicz and Gellert, 2009). Similarly, ED was reported in 52% of men undergoing peritoneal dialysis (Lai et al, 2007). The presence of depressive symptoms, highly prevalent in hemodialysis patients, is an independent factor of sexual dysfunction in male hemodialysis patients (Peng et al, 2007). Significant improvement of sexual function has been reported after kidney transplantation (Tavallai et al, 2009). Nevertheless, in a report of 182 men who had undergone kidney transplantation, Espinoza and colleagues (2006) noted that 49% of men continued to have ED; 33% of men had normal sexual function, and 18% had no sexual activity. Many of the effects of uremia can potentially contribute to the development of ED, including disturbance of the hypothalamic–pituitary–testicular axis, hyperprolactinemia, accelerated atherosclerotic disease, and psychological factors (Ayub and Fletcher, 2000).

Bagcivan and colleagues (2003) suggest that ED may be due to either decreased production or reduced bioavailability of endogenous NO. Evidence from animal models of chronic uremia suggests that a decrease in functional NO may be responsible for vascular side effects including ED.

Evidence of autonomic neuropathy as a factor contributing to ED in men with chronic renal failure comes from studies that found a high rate of abnormality in vascular and bulbocavernosus reflexes, suggesting nerve dysfunction (Campese et al, 1982; Vita et al, 1999). Neuropathy is a common complication of end-stage kidney disease, typically manifesting as a distal symmetrical process with insidious onset progressing over months. Neuropathy has been estimated to occur in 60% to 100% of patients on dialysis. Nerves of uremic patients have been shown to exist in a chronically depolarized state before initiation of dialysis, with subsequent improvement and normalization of resting membrane potential after initiation of dialysis. The degree of depolarization correlates with serum K^+ , suggesting that chronic hyperkalemic depolarization plays an important role in the development of nerve dysfunction in end-stage kidney disease (Krishnan and Kiernan, 2007). Investigation of cavernous vascular function in 20 men undergoing renal replacement therapy showed that 80% had both arterial insufficiency and veno-occlusive dysfunction (Kaufman et al, 1994). A link between impairment of the NO–cGMP pathway relating to failure of cavernous relaxation is provided by the finding of increased serum levels of ADMA in uremic patients (Kielstein and Zoccali, 2005).

Patients with severe pulmonary disease often fear aggravating dyspnea during sexual intercourse. Patients with angina, heart failure, or myocardial infarction can become impotent from anxiety, depression, or arterial insufficiency. HIV infection itself is the strongest predictor of ED, and many factors related to the infection—fear of virus transmission, changes in body image, HIV-related comorbidities, infection stigma, obligatory condom use—impair erectile function (Santi et al, 2014). In two large European studies, Corona et al (2012) reported that overt hyperthyroidism was associated with an increased risk of severe ED. Conversely, no association between primary hypothyroidism and ED was observed. Other systemic diseases, such as cirrhosis of the liver, scleroderma, chronic debilitation, and cachexia, are also known to cause ED.

Primary Erectile Dysfunction

Primary ED refers to a lifelong inability to initiate and/or maintain erections beginning with the first sexual encounter. Although most cases are due to psychological factors, a few afflicted men have a physical cause resulting from maldevelopment of the penis or the blood and nerve supply. Primary psychological dysfunction is usually related to anxiety about sexual performance

stemming from adverse childhood events, traumatic early sexual experience, or misinformation. Endocrine abnormalities, particularly low testosterone levels, may also be implicated in primary ED, although decreased sex drive is likely to be the main symptom. Evidence to support these concepts is confined to observation studies with varying numbers of cases. The largest study described 67 patients, of whom 10 (15%) had a predominantly psychological cause (Stief et al, 1989b). Patients with physical abnormalities had a variety of neurologic, arterial, and veno-occlusive dysfunction.

Micropenis. Symmetrical hypoplasia of the phallus, micropenis, is often related to urethral developmental abnormalities such as hypospadias and epispadias (Reilly and Woodhouse, 1989) or endocrine deficiency. The erectile tissue in such cases often functions normally; sexual dysfunction usually relates to lack of penile length or the degree of chordee, rather than to ED (Woodhouse, 1998).

Vascular Abnormalities. Primary ED in the presence of an externally normal phallus is unusual. Authors have described structural abnormalities of the cavernous tissue, such as absence (Teloken et al, 1993) or replacement by fibrous tissue (Aboseif et al, 1992). Other authors have found vascular abnormalities, including hypoplasia of the cavernous arteries (Montague et al, 1995) or veno-occlusive dysfunction owing to aberrant cavernous venous drainage (Lue, 1999). The underlying cause of these congenital abnormalities is unknown. Treatment in most cases has been vascular surgery or implantation of a penile prosthesis.

KEY POINTS: OTHER CAUSES OF ERECTILE DYSFUNCTION

- Aging is the most important contributing factor to ED. The aging process can affect the central regulatory mechanism, hormonal and neural function, and penile structure.
- Diabetes mellitus and metabolic syndrome may affect multiple organ systems and cause premature aging of central and peripheral structures and molecules that regulate erectile process.
- The diseases that cause chronic renal failure may also cause ED, and the condition may persist despite successful renal transplantation.
- Primary ED may be due to psychogenic cause, inexperience, congenital arterial insufficiency, or abnormal venous channels.

KEY POINTS: PATHOPHYSIOLOGY

- The prevalence of ED increases with age and concomitant medical diseases. The incidence is about 25 to 30 cases per 1000 person-years.
- ED is a symptom of many underlying conditions and diseases.
- Any condition that affects penile nerve, artery, endothelium, smooth muscle, or tunica albuginea can cause ED.
- Endothelial dysfunction seems to be a common final pathway to ED in patients with hyperlipidemia, diabetes mellitus, hypertension, and chronic renal failure.
- Drugs most commonly associated with ED include antianesthetics, antidepressants, and antihypertensives.

PERSPECTIVES

The past two decades have seen a continuing explosion of new information on the physiology of penile erection and the pathophysiology of ED. These new discoveries not only enhance our understanding of the disease process but also provide a solid basis for improving diagnosis and treatment. We can expect that the application of new research tools and information in molecular

biology, signal transduction, growth factors, microarrays, and stem cells will bring the investigation of erectile function and ED to an even higher level in the near future.

Historical Perspective

Public Health Significance

Management Principles

Diagnostic Evaluation

Specialized Evaluation and Testing

Treatment Considerations

Future Directions

HISTORICAL PERSPECTIVE

Erectile dysfunction (ED) management has evolved into a mature clinical discipline in the past few decades, owing to steady, considerable progress made in the basic science, epidemiology, clinical investigation, and health services research within this dynamic field. The field has advanced from its well-notioned beginnings of psychoanalysis and sex therapy, accompanied by the use of aphrodisiacs, herbal supplements, and hormonal treatments, typifying the knowledge and approach to clinical practice in the 1970s, to an increasingly structured, balanced, and evidence-based process of clinical evaluation and intervention of the contemporary era (Table 27-1).

Well-grounded ED management principles, premised on the highest clinical standards of ethics, quality, safety, and cost-effectiveness, are now well accepted by the scientific and clinical community in sexual medicine. These “guidelines” have derived from rigorous and timely review, organization, and reassessments of the constantly evolving body of knowledge in this field performed by assorted consensus bodies representing the spectrum of international and interdisciplinary authorities in sexual medicine. Most notably, the International Consultations on Sexual Medicine (ICSM), cosponsored variously by the World Health Organization, International Consultation on Urological Diseases, American Urological Association, Société Internationale D’Urologie, and the International Society for Sexual Medicine, have served this role and have published topical proceedings (Jardin et al, 2000; Lue et al, 2004; Montorsi et al, 2010).

PUBLIC HEALTH SIGNIFICANCE

ED is a medical condition of major health significance, with implications that extend beyond treating the occasionally presenting patient who possesses a problem of seemingly non-life-threatening magnitude. The value of properly assessing and managing ED relates not only to affected individuals and their partners but also to society as a whole, and its scope encompasses physical and mental wellness aspects related to addressing (or failing to address) the sexual dysfunction, concurrent disease management issues, as well as its socioeconomic burden.

Epidemiology

Epidemiologic investigation, which specifies that study results are readily generalized to the overall male population, has provided powerful information regarding the nature, etiology, and prognostic ramifications of ED. As the most thoroughly studied sexual

dysfunction in the context of epidemiologic research, ED is estimated to carry an overall adult male (older than 20 years of age) prevalence rate of 10% to 20% worldwide, with the majority of studies reporting a rate closer to 20% (Derogatis and Burnett, 2008; Lewis et al, 2010). It is acknowledged that an age correlation exists for the prevalence of ED, with a worldwide prevalence of 1% to 10% for men younger than the age of 40 years, as high as 15% for men age 40 to 49 years, as high as 30% for men age 50 to 59 years, as high as 40% for men 60 to 69 years, and 50% to 100% for men in their 70s and 80s (Lewis et al, 2010). It was estimated that there were more than 152 million men worldwide who experienced ED in 1995, with a projection of the prevalence reaching approximately 322 million men having ED by 2025 (Aytac et al, 1999). This trend is maintained irrespective of racial/ethnic background or geographic region.

Current data have also confirmed that the prevalence of ED mounts with the presence of comorbid medical conditions, which include type 2 diabetes mellitus, obesity, cardiovascular disease, hypertension, dyslipidemia, depression, and prostate disease/benign prostatic hyperplasia (Braun et al, 2000; Martin-Morales et al, 2001; Nicolosi et al, 2004; Rosen et al, 2004c; Saigal et al, 2006; Laumann et al, 2007; Selvin et al, 2007). This correlation has supported the premise that ED and comorbid medical conditions share pathophysiologic mechanisms, such as endothelial dysfunction, arterial occlusion, and systemic inflammation (Solomon et al, 2003; Montorsi et al, 2004; Billups, 2005; Ganz, 2005; Kloner, 2005; Guay, 2007).

Novel disease-risk relationships for ED have been described, likely also exhibiting such concomitant pathophysiologic mechanistic associations as endothelial dysfunction and systemic inflammation. These disease relationships include epilepsy (Keller et al, 2012b), sensorineural hearing loss (Keller et al, 2012a), open-angle glaucoma (Chung et al, 2012a), urinary calculi (Chung et al, 2011), psoriasis (Chung et al, 2012b), atopic dermatitis (Chung et al, 2012d), chronic periodontitis (Keller et al, 2012d), viral hepatitis (Chung et al, 2012c), varicocele (Keller et al, 2012c), and gastric ulcers (Keller et al, 2012e).

Although they are few in number, prospectively conducted longitudinal studies have documented the true incidence and disease-risk relationships for ED. In one study, a crude ED incidence rate was 25.9 cases/1000 man-years among men aged 40 to 69 years (Johannes et al, 2000). According to another study, incident ED statistics were 57% at 5 years and 65% at 7 years in men 55 years or older (Thompson et al, 2005). Such studies have uniquely affirmed predictors for the development of ED, which include age, lower education, diabetes, cardiovascular disease, hypertension, cigarette smoking, cigar smoking, passive exposure to cigarette smoke, and overweight condition (Feldman et al, 2000; Johannes et al, 2000; Inman et al, 2009).

However, the strength of the risk association is also gauged from the opposite analytic direction, and incident ED may indeed inform the risk of subsequent disease morbidity and mortality. This relationship has been best demonstrated so far with respect to cardiovascular disease. The placebo arm of the Prostate Cancer Prevention Trial found that ED is a sentinel for future risk of cardiovascular events, comparable to that of current cigarette smoking or a family history of myocardial infarction (Thompson et al, 2005). This study established that men with ED were 45% more likely than men without ED to experience a cardiac event after 5 years of follow-up (Thompson et al, 2005). In another population-based study of community-dwelling men followed longitudinally, ED was associated with an approximately 80% higher risk of subsequent coronary artery disease at 10 years (Inman et al, 2009). In a long-term follow-up (15 years) of the Massachusetts Male Aging Study (Feldman et al, 1994), ED was found to be positively associated with subsequent all-cause and cardiovascular disease mortality and constituted a risk in this regard similar to that of conventional risk factors, such as increased body mass index, diabetes, and hypertension (Araujo et al, 2009). It is an increasingly recognized and striking observation, made in epidemiologic studies demonstrating the risk association of ED with cardiovascular events, that the development of ED at a younger age heightens this particular risk (Chew et al, 2010; Miner et al, 2012; Vlachopoulos et al, 2013).

Recent meta-analyses of longitudinal studies have supported the findings of earlier reports and have provided relative risk estimates. A meta-analysis of seven prospective cohort studies provided adjusted relative risks for ED subjects compared with healthy subjects, calculating 1.47-fold increased cardiovascular disease events overall and 1.23-fold increased all-cause mortality (Guo et al, 2010). Another meta-analysis of 12 cohort studies calculated overall combined relative risk for men with ED compared with the reference group to be 1.48 with cardiovascular disease, 1.46 for coronary heart disease, 1.35 for stroke, and 1.19 for all-cause mortality (Dong et al, 2011). A further meta-analysis comprising 14 studies documented relative risk of 1.44 for cardiovascular mortality, 1.19 for myocardial infarction, 1.62 for cerebrovascular events, and 1.25 for all-cause mortality for men with ED versus those without ED (Vlachopoulos et al, 2013).

Besides a predictive relationship of cardiovascular disease based on incident ED, a similar relationship has been suggested with respect to carcinogenesis risk. The "Longitudinal Health Insurance Database" study in Taiwan showed that cancer risk was 1.42-fold higher in ED patients than in patients without ED during a 5-year follow-up, after adjusting for socioeconomic and comorbid health variables (Chung et al, 2011).

These compelling data regarding occurrence rates and risk factors for ED contribute greatly toward an understanding of the importance of this medical condition. **The subject of ED offers a veritable clinical barometer of overall male health status, and efforts geared toward advancing its management are immediately consequential for disease prevention, health promotion, and survival improvement.**

Health Policy

Sexual dysfunctions and ED specifically have taken on increasing importance with respect to their socioeconomic impact. **In addition to its medical comorbidity associations, ED is recognized to affect adversely quality of life, to decrease occupational productivity, and to increase the use of health care resources (Krane et al, 1989; Litwin et al, 1998).** Because of the heightened ease of use and availability of effective first-line treatments combined with a growing societal awareness of ED and an acceptance of its treatment, it is understandable that a trend toward increased use of health care services surrounding ED has been observed (Wessells et al, 2007; Polinski and Kesselheim, 2011).

ED can be included among a host of urologic diseases having a substantial burden on the public financially. Total expenditures for outpatient clinical management of ED (exclusive of pharmaceutical costs) in the United States in the year 2000 approximated \$330 million, ranking it the ninth most costly among the most frequent urologic diagnoses (Litwin et al, 2005). By contrast, this cost was approximately \$185 million in 1994 (Wessells et al, 2007). Individual-level expenditures on an annual basis associated with an ED diagnosis (inclusive of pharmaceutical costs) among affected 18- to 64-year-old males in the United States in 2002 were calculated to be \$1107 (Wessells et al, 2007). The Congressional Budget Office estimate of government expense for ED drugs in 2005 was \$2 billion for the subsequent 10 years (Polinski and Kesselheim, 2011). These data have enormous implications for governmental as well as nongovernmental agencies in the United States and worldwide, whose work must consider the practical distribution and fiscal allocation of health care services for ED. Some experts have accordingly urged an account of the medical necessity and cost of ED therapy when formulating grounds for insurance coverage (Polinski and Kesselheim, 2011). However, evidence points to rational coverage for ED therapy, and in fact a significantly lower use of this therapy has been shown as compared to ED prevalence (Hornbrook and Holup, 2011). Arguments support the fact that ED is not a frivolous indication for clinical intervention, having quality-of-life and well-being implications as well as importance with respect to health and life preservation.

KEY POINTS: EPIDEMIOLOGY AND HEALTH POLICY

- Approximately 20% of adult men worldwide experience ED.
- Risk factors for ED include increasing age and presence of comorbid medical conditions such as type 2 diabetes mellitus, obesity, cardiovascular disease, hypertension, dyslipidemia, depression, and prostate disease/benign prostatic hyperplasia.
- Outcomes research has shown that ED is meritorious for clinical intervention, having quality-of-life and well-being implications as well as importance with respect to health and life preservation.
- ED ranks among the top 10 most costly urologic diagnoses in the United States and must be included in considerations for fiscal allocation of health care services.

MANAGEMENT PRINCIPLES

The approach to the evaluation and treatment of ED is most assuredly different from that of many other urologic diseases in several basic respects. The diagnosis of ED customarily involves an acknowledgment of the subjective complaint of erectile inability by the patient (or patient and partner), and extensive diagnostic procedures are generally not required to proffer the diagnosis. Additionally, current first-line intervention in the form of effective oral pharmacotherapy is easily prescribed and administered and is frequently successful for the majority of patients. However, notwithstanding the semblance that the management of ED is fairly uncomplicated, it is a structured process that critically incorporates several clinical practice concepts for bringing the best therapeutic outcomes to patients.

Early Detection

Epidemiologic and clinical investigation has suggested that many patients with ED retain adverse clinical conditions and also lifestyle factors (e.g., diabetes, cardiovascular disease, prostate disease, overweight condition, current cigarette smoking, and physical inactivity) that potentially compromise erectile function (Saigal et al, 2006; Laumann et al, 2007; Selvin et al, 2007; Lewis et al, 2010). The extent of these risk factors comprises an increased global cardiometabolic risk profile in patients with ED (Miner et al, 2012; Nehra et al, 2012). Calculated odds ratios underscore the extent to which various ED risk factors correlate with ED (Table 27-2). These data support the contention that patients with identifiable ED risk factors likely experience the sexual dysfunction currently or will eventually develop it at some time. Clinical screening of such patients based on these indications is advantageous in allowing opportunities to diagnose and treat ED.

Growing evidence has also suggested that a patient's genotype influences the risk of developing ED, consistent with proposals that both molecular and genetic mechanisms account for the ED phenotype (Andersen et al, 2011; Lippi et al, 2012). This concept fits with the perspective that genetically determined biomarkers will eventually be defined to assess ED risk profile as well as level of responsiveness to a specific ED therapy in the advancing era of precision medicine.

Medication use has also been associated with ED in up to 25% of presentations (Keene and Davies, 1999; Francis et al, 2007). The most commonly implicated classes of drug include antihypertensive drugs, such as thiazide diuretics and β -adrenoceptor antagonists, and psychotherapeutic drugs, particularly selective serotonin reuptake inhibitor (SSRI) antidepressants. Table 27-3 lists several drug classes commonly associated with ED. It is important to recognize that medications may affect other components of the male sexual response cycle including sexual desire, arousal, and orgasm, which secondarily hampers erectile function. Of additional importance, the assignment of causation of ED for any particular medication is conditional, requiring that an increased prevalence exists in the

TABLE 27-2 Major Erectile Dysfunction Risk Factors

CONDITION	MULTIVARIATE ADJUSTED ODDS RATIO
Diabetes mellitus	2.9

TABLE 27-3 Drugs Associated with Erectile Dysfunction

CLASS	SPECIFIC AGENTS
Antihypertensives	Thiazide diuretics, nonselective β -blockers
Antidepressants	Tricyclics; selective serotonin reuptake inhibitors
Antipsychotics	Phenothiazines
Antiandrogens	Nonsteroidal (flutamide); steroidal (cyproterone acetate); luteinizing hormone-releasing hormone analogues
Antiulcer drugs	Histamine H ₂ receptor antagonists (cimetidine)
Cytotoxic agents	Cyclophosphamide, methotrexate
Opiates	Morphine

target population compared with the placebo group after stratification for known risk factors or compared to another drug with an equivalent therapeutic effect, and, further, a credible physiologic mechanism should be established experimentally (Sáenz de Tejada et al, 2005).

Goal-Directed Management

A goal-directed approach to the management of patients with ED has largely been practiced in the field throughout the decades since Lue's original description (Lue, 1990). The approach dictates that the diagnostic evaluation and therapeutic plan relates to the individual patient's presentation and manner of deriving satisfaction, in accordance with a patient-centered framework (Hatzichristou et al, 2010). The basic aim of goal-directed management is to allow the patient or couple to make an informed selection of the preferred therapy for sexual fulfillment based on a sound understanding of all treatment options after completing a thorough discussion with the treating clinician. The approach recognizes that patients vary in their acceptance of their sexual disorders and in their interest in pursuing management. Their decisions accordingly follow individual preferences, needs, and expectations regarding management options. Evaluations of this approach have affirmed its utility and demonstrated that patient therapeutic preferences accord with the least invasive forms of therapy (Jarow et al, 1996; Hanash, 1997).

Role of Partner Interview

The partner interview is a critical component in initiating management of ED. Partner interviews have been shown to impact diagnosis and treatment in as much as 58% of cases (Tiefer and Schuetz-Mueller, 1995; Chun and Carson, 2001). The partner may be the source of important information that guides optimal intervention and response to therapy. The partner may share a new and different perspective on sexual issues affecting the couple, might provide insight into the quality of the couple's relationship, and might relate his/her role in the sexual dysfunction (Speckens et al, 1995; Fisher et al, 2009). The partner's involvement and attitude may also impact the patient's initiation of and adherence to therapy (Jackson and Lue, 1998; Fisher et al, 2005).

An important additional consideration is that partners' well-being may be affected by the patients' ED conditions. Studies have shown that women partners of men with ED are themselves more likely to have sexual dysfunction or to cease sexual activity entirely (Ichikawa et al, 2004; Montorsi and Althof, 2004; Fisher et al, 2005; Sand and Fisher, 2007). This observation further prompts the facilitatory role of the partner in ED management, which maximizes the success of therapy and inherently the satisfaction of the couple.

In practice, and as necessary, additional office visits, during which the partner accompanies the patient and the patient communicates educational information to the partner, are recommended techniques for involving partners in ED management (Dean et al, 2008).

Cardiac Risk Assessment

The frequent coexistence of ED and cardiovascular disease, as established by clinical epidemiologic study and by basic science research, has steered ED management to include procedures that account for the ED patient's cardiovascular health risks. The Princeton Consensus Conferences, a multidisciplinary forum convened successively on three occasions since the early 2000s, have emphasized the link between sexual activity and cardiac risk and have pronounced that all men with ED, even in the absence of manifesting cardiac symptoms, should be regarded as having potential risks for cardiovascular disease (DeBusk et al, 2000; Kostis et al, 2005; Jackson et al, 2006b; Nehra et al, 2012).

According to the Princeton Consensus expert panel guidelines, ED patients are recommended to undergo a full medical assessment with stratification of cardiovascular risk as high, medium, or low (Fig. 27-1). Patients classified as having a high risk would be those with unstable or refractory angina, a recent history of myocardial infarction, certain arrhythmias, or uncontrolled hypertension. For these patients, sexual activity with any particular ED therapy should be deferred until the cardiac condition is stabilized. Such patients should ideally undergo cardiologic referral for cardiovascular stress testing and subsequent risk-reduction therapy. Importantly, even patients at low risk for cardiovascular events should receive the minimum recommendations of cardiovascular disease management. Basic intervention includes counseling for lifestyle modifications such as increased physical activity and improved weight control combined with regular health monitoring by the patient's general practitioner (Kostis et al, 2005). A more comprehensive approach specifies cardiovascular risk reduction and affirmation of exercise tolerance for sexual activity following noninvasive cardiovascular risk assessment that may involve a specialist or collaborative medical team having such expertise (Nehra et al, 2012).

Step-Care Approach

Practitioners of ED management have always sought a rational approach for implementing diagnostic and therapeutic options. The "Process of Care Model for Erectile Dysfunction" was proposed as a stepwise methodology, combining processes, actions,

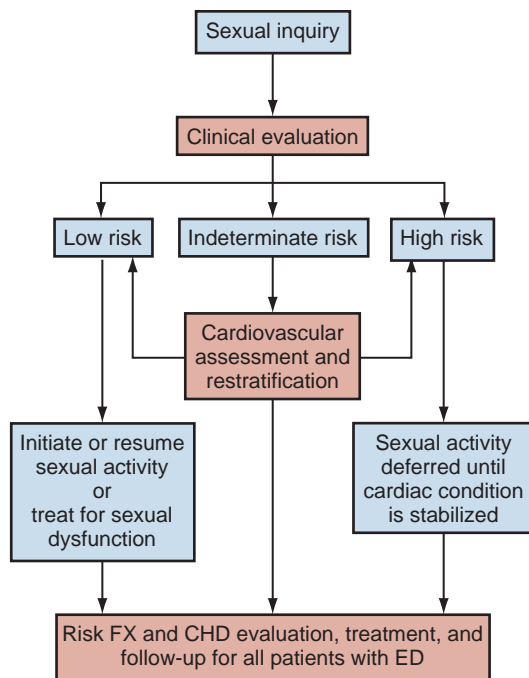

Figure 27-1. Algorithm for evaluation of the patient with cardiovascular disease recommended by the Second Princeton Panel. CHD, coronary heart disease; ED, erectile dysfunction; FX, factors.

and outcomes in the management of the ED patient (Process of Care Consensus Panel, 1999). It specified an algorithm for therapeutic decision making that takes into account patient needs and preferences (goal-directed management), although it was also based on specific criteria such as ease of administration, reversibility, relative invasiveness, and cost of therapies. This algorithm presented a strategy of staged therapy (i.e., first-, second-, and third-line interventions), which ranged from lifestyle modification to surgery. In concept, the scheme has been borrowed and endorsed by other consensus panels that acknowledged the purpose of patient education and counseling along with medical therapies as initial forms of ED management in common practice (Montague et al, 2005; Hatzichristou et al, 2010).

Shared Decision Making and Treatment Planning

The therapeutic plan may vary for every patient and couple and it ultimately depends on a host of factors including patient considerations as well as clinical indications and contraindications. An informed decision-making process should dictate the best therapeutic option. It follows a balanced and thorough discussion led by the clinician of all treatment options, both medical and nonmedical, and their expected advantages and disadvantages. Perceived risks and benefits, which may be influenced by the individual clinical situation, should be weighed. It is understood that the patient may appropriately select a preferred treatment option without necessarily adhering to a strictly prescribed succession of attempted therapies. Indeed, the patient may elect to defer treatment altogether. Whatever the patient (or couple) chooses, this option can then be pursued within the boundaries of safety, under the supportive partnership of his clinician.

Specialist Referral

The advent of effective oral pharmacotherapy for ED has enabled many primary practitioners to feel comfortable with managing the majority of clinical presentations of ED. At the same time, it is understood that situations arise in which the patient or primary

practitioner may request the assistance of a consultant/specialist (e.g., cardiologist, endocrinologist, psychologist, or urologist) for further diagnostic evaluation and treatment beyond the boundaries of initial management (*Process of Care Consensus Panel, 1999*). Such referrals may be required for individuals with complicated or atypical presentations of ED, representing diagnostic challenges that exceed common clinical practices of nonspecialists. Specialized evaluation and management potentially offer improved therapeutic outcomes for these presentations.

Generally recommended indications for specialized evaluations and associated consultants are: failure of initial treatment, referred to a urologist; younger patients with a history of pelvic or perineal trauma, referred to a urologist; patients with significant penile deformity (e.g., Peyronie disease, congenital chordee), referred to a urologist; complicated endocrinopathies (e.g., secondary hypogonadism, pituitary adenoma), referred to an endocrinologist; complicated psychiatric or psychosexual disorders (e.g., refractory depression, hypoactive sexual desire), referred to a psychiatrist; presentations requiring vascular or neurosurgical intervention (e.g., aortic aneurysm, lumbosacral disk disease), referred to a vascular surgeon or neurosurgeon, respectively; medical/legal reasons (e.g., workman's compensation claims), referred to a urologist.

A caveat is that effort should be made at the time of referral to ensure that patients are fully informed about the rationale, costs, potential risks, and potential outcomes of the referral and possible additional procedures. This recommendation is made in accordance with the principles of patient-centered medicine, by which patients (and partners where possible) should be included in the decision-making process.

Follow-up Care

Follow-up care is an essential part of ED management and should not be overlooked. The objectives of this action are manifold. A primary basis is to ensure continual success with the therapeutic outcome. It has been shown that treatment discontinuation occurs at high rates among patients who are not reassessed regularly (*Albaugh et al, 2002*). Additional purposes are to reassess medical and psychosocial conditions adversely impacting ED and success of therapy, evaluate the need for dosage titration or treatment substitution, and monitor adverse drug interactions or drug-interaction effects. As always, follow-up attention offers educational opportunities for patient and partner with regard to addressing sexual health concerns as well as lending guidance for related health care matters.

DIAGNOSTIC EVALUATION

The cornerstone in the evaluation of ED involves a detailed case history, preferably taken from patient and partner, physical examination, and proper laboratory tests (*Fig. 27-2*). The diagnosis can be submitted based on an individual's report of consistent inability to attain and maintain an erection of the penis sufficient to permit satisfactory sexual intercourse (*NIH Consensus Statement, 1992; Lewis et al, 2004*). It is noteworthy that the original National Institutes of Health definition did not specify a parameter for the duration of symptoms to accept the diagnosis. Subsequent organizational statements did apply a 3-month interval as a minimal requirement diagnostically, except for cases of trauma or surgically induced ED (*Lewis et al, 2004*).

Sexual, Medical, and Psychosocial History

The comprehensive assessment of any sexual problem begins with the performance of a detailed case history including sexual, medical, and psychosocial components. The clinician may use brief checklists or questionnaires for the purpose of recognizing the problem and initiating its evaluation, although he/she should routinely perform a detailed interview to understand the nature of the sexual complaint. The sexual history component in particular should be elicited with utmost sensitivity, given the intrapersonal and interpersonal aspects of sexual dysfunction (*Rosen et al, 2004; Althof et al, 2013*). Additional emphasis has been directed toward providing cultural competence when interacting with patients (*Hatzichristou et al, 2010*). All discussion of sexual matters is done privately and confidentially, and the clinician is required to express trust and concern as well as a nonjudgmental manner that epitomizes the doctor-patient relationship. The clinician should not assume that every patient is involved in a monogamous, heterosexual relationship. However, the situation may be presented whereby the partner can be interviewed, and this opportunity may be used, with the approval of the patient, to corroborate aspects of the clinical history and to confirm mutual therapeutic goals.

Sexual History

The sexual history is the central component of the clinical history and serves to confirm the patient's sexual dysfunction complaint of ED. Objectives of the interview are also to delineate the problem according to such features as its onset, duration, conditions, severity, and etiology. The conditions of the problem are often

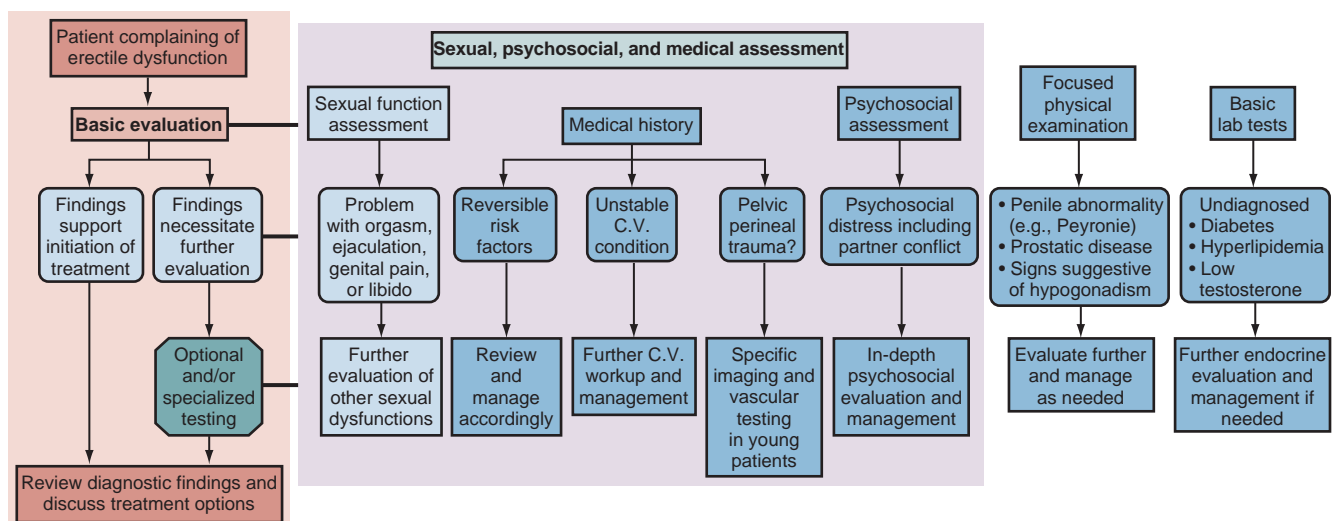

Figure 27-2. Diagnostic algorithm for erectile dysfunction (ED) recommended by the International Consultations on Sexual Medicine. C.V., cardiovascular.

determined by reviewing circumstances that facilitate or hinder erectile function. Circumstances for achievable erections include stimuli used during sexual encounters, erections on awakening, and the role of self-stimulation. Circumstances associated with erectile difficulty include performance anxiety, inability to perform with a designated partner, and motivational factors affecting lovemaking. Other pertinent issues include availability, interest and health of the partner, changes in medical status or other events relating to the onset of ED, and previous attempts to manage the problem by the patient or another caregiver.

The severity of ED can be defined as mild, moderate, or severe/complete, according to increasing degrees of loss of penile rigidity and the associated interference with sexual activity. For instance, mild ED may refer to a minimally decreased ability to attain and/or maintain an erection with intermittent satisfactory sexual performance, moderate ED may refer to a minimally decreased ability to attain and/or maintain an erection with infrequent satisfactory sexual performance, and severe ED may refer to a substantially decreased ability to attain and/or maintain an erection with rare or absent satisfactory performance.

The potential etiology of ED is commonly probed and may be categorized as psychogenic, organic, or mixed according to whether there is a presumed psychological or interpersonal determinant (psychogenic), a specific endocrinologic, neurologic, or cardiovascular cause (organic), or the coexistence of psychological or relationship factors and organic causes (mixed) (Table 27-4) (Ralph and McNicholas, 2000; Hatzichristou et al, 2010). It is accepted that many times ED cannot be fully dichotomized into psychogenic and organic categories. However, its characterization by a predominant etiologic basis may nonetheless facilitate therapeutic objectives. The interview should also assess whether ED is the primary source of the presenting complaint or secondary to some other aspect of the sexual response cycle (e.g., desire, ejaculation, orgasm) that may also relate to the clinical presentation (Rosen, 2004a). The association of decreased arousal, if present, may be explored as well and evaluated to determine whether it preceded or was incidental to the development of ED.

Medical History

The medical history primarily serves to identify and evaluate predictors and risk factors associated with ED. The main objective is to explore the role of possibly related or underlying medical conditions and to ascertain the existence of comorbidities. Recognition of the association between medical conditions and ED not only may lend insight into the possible basis for the ED, which may guide the choice of therapy, but it may also specify reversible or treatable factors associated with ED that may be corrected with an expectation of improving the level of erectile function.

Medical conditions associated with ED include disease states (e.g., type 2 diabetes mellitus, cardiovascular disease, hypertension, dyslipidemia, neurologic disease, hypogonadism, thyroid disorders), consequences of trauma involving aspects of the body, pelvis, or genitalia (e.g., spinal cord injury, pelvic surgery or radiation, sexual injury), and also side effects of medications or recreational substances that disturb biochemical processes of penile erection. Age is recorded, in accordance with the well-known association between aging and ED. It is important that comorbidities (e.g.,

depression, anxiety, anger) are registered because of their bidirectional relationship with ED.

Psychosocial History

The intake of psychosocial history is a necessary part of the clinical history. The very best sexual performance most assuredly implies wellness of mind and body acting together, and unstable psychosocial circumstances of both intrapersonal and interpersonal contexts may adversely affect sexual function. Accordingly, the presence and interaction of mental health problems, emotional stressors, and interpersonal relationship difficulties, both past and present, should be ascertained. Additional questions may be asked relating to occupational status, financial security, family life, and social support, which may also influence sexual function.

Physical Examination

The physical examination is a highly recommended component of the comprehensive assessment of sexual dysfunctions and complements the clinical case history (Ghanem et al, 2013). It may show possible etiologies for ED.

This evaluation consists of basic anthropometrics (i.e., height, weight, waist circumference), assessment of body habitus (appearance of secondary sexual characteristics), and examination of relevant body parts pertaining to cardiovascular, neurologic, and genital systems, with a particular focus on the external genitalia. The observation of a classically distinctive body habitus consistent with Kallman or Klinefelter syndrome or obvious physical signs of hypogonadism, such as gynecomastia and general poor masculine development, may suggest an endocrinologic basis for ED.

Findings of obesity, elevated blood pressure, or abnormal femoral or pedal pulses, all signs representative of cardiovascular disease, convey a potential vascular causation. Findings of abnormal genital and perineal sensation or bulbocavernosus reflex (squeezing of the glans penis resulting in contraction of the bulbocavernosus muscle detected by a finger in the anus) may indicate the presence of a peripheral neuropathy in association with a neurologic disorder or diabetes.

Detection of a penile deformity, such as micropenis, congenital chordee, or Peyronie disease-related fibrous plaques in the corpora cavernosa, supports the possibility that a physical impediment accounts for ED. Genital examination findings of abnormal position, size, and consistency of testes may also suggest hypogonadism and would indicate that ED exists on endocrinologic grounds.

Questionnaires and Sexual Function Symptom Scores

Self-administered ED questionnaires are extremely useful adjuncts to the case history, and they concur with the patient's self-report in establishing the diagnosis. Questionnaires supplied early in the field were very detailed, such as the Derogatis Sexual Function Inventory (245 items) (Derogatis and Melisaratos, 1979) and the Golombok Rust Inventory of Sexual Satisfaction (GRISS) (28 items) (Rust and Golombok, 1986), and they commonly aimed to differentiate psychogenic and nonpsychogenic ED or to evaluate sexual functioning in the context of the couple. Instruments developed more recently were implemented primarily in clinical trials associated with new drug development, and they particularly captured efficacy end points including sexual interest, performance, and satisfaction. However, as part of pattern shifts of practice that have occurred in ED management in recent years, there has been a growing emphasis on and application of patient self-reported instruments for clinical practice. These self-report measures have been meant to be brief and practical and to serve in documenting the presence and severity of ED, and the responsiveness of ED to treatment.

The most widely referenced instruments include the International Index of Erectile Function (IIEF) by Rosen and associates (1997), the Brief Male Sexual Function Inventory (BMSFI) by

TABLE 27-4 Classification of Erectile Dysfunction

PSYCHOGENIC	ORGANIC
Sudden onset	Gradual onset
Complete immediate loss	Incremental progression
Situational dysfunction	Global dysfunction
Waking erections present	Waking erections poor/absent

O'Leary and colleagues (1995), the Center for Marital and Sexual Health Sexual Functioning Questionnaire by Glick and associates (1997), the Changes in Sexual Functioning Questionnaire by Clayton and associates (1997), and the Erectile Dysfunction Inventory of Treatment Satisfaction (EDITS) by Althof and colleagues (1999). The IIEF, which contains 15 items that address and quantify

five domains: erectile function, orgasmic function, sexual desire, intercourse satisfaction, and overall satisfaction, is the most widely used questionnaire (Fig. 27-3). An abridged 5-item version of this instrument, the IIEF-5, has been useful to clinicians in routine clinical practice specifically for the evaluation of ED (Rosen et al, 1999a). The instrument classifies ED severity into five categories: severe

Figure 27-3. International Index of Erectile Function Questionnaire.

(5 to 7), moderate (8 to 11), mild to moderate (12 to 16), mild (17 to 21), and no ED (22 to 25). The Male Sexual Health Questionnaire offers another instrument that assesses core components of male sexual function (i.e., desire, erection, ejaculation, satisfaction) and is useful in both clinical and research settings (Rosen et al, 2004b). The Sexual Experience Questionnaire is a brief but comprehensive tool for evaluating health-related quality-of-life concepts, and it comprises erection, individual satisfaction, and couple satisfaction domains (Mulhall et al, 2008).

A known limitation of self-administered questionnaires is that they do not distinguish an etiologic basis for ED, that is, they do not differentiate among the various causes of ED (Blander et al, 1999; Kassouf and Carrier, 2003). Further, they may not sufficiently indicate the severity of ED that is evidenced on objective grounds (Tokatli et al, 2006). Although the exact nature of the ED diagnosis arguably is not absolutely necessary to initiate ED treatment today with current management options, it is understood that further clinical evaluation with diagnostic tests may be required to discern the basis and extent of the ED by system (e.g., vascular, neurologic, endocrinologic) and take action that may be most effective and possibly corrective.

Cardiovascular Risk Assessment Tools

A trend in ED assessment is the application of cardiovascular disease-risk prediction models, which are used as scoring instruments to aid in the assessment of any man evaluated for ED (Nehra et al, 2013). Such models as the Framingham Risk Score or an alternate global risk score, which incorporate such cardiovascular predictive variables as family history of coronary heart disease, body mass index, and metabolic laboratory biomarkers, offer a powerful initial step to characterize and possibly mitigate cardiovascular risk in this clinical setting.

Laboratory Tests

Appropriate laboratory testing can be considered part of a systematic clinical evaluation for individuals presenting with ED (Ghanem et al, 2013). Such evaluation may confirm or define etiologic medical conditions associated with the sexual dysfunction. At times, it may identify treatable conditions or previously undetected disease states that may contribute to ED. A standardized panel of tests can be offered for the man presenting routinely with sexual dysfunction including ED. Further laboratory testing can be tailored to the clinical situation. Similarly, specialized endocrinologic assessment can be performed when indicated for select clinical presentations.

Recommended laboratory tests for men with sexual problems typically include serum chemistries, fasting glucose, complete blood count, lipid profile, and serum total testosterone. Total testosterone, measured from a morning-time blood draw, serves to screen androgenic status, and, if abnormally low, serum-free (or bioavailable) testosterone and luteinizing hormone (LH) should be measured. Prolactin measurement may also be done for hormonal assessment. Thyroid function tests may be performed at the clinician's discretion. Serum prostate-specific antigen (PSA) testing is performed as needed if there is a suspicion of prostate pathology that might be promoted by exogenously administered testosterone. Dipstick analysis of urine may show glucosuria, which suggests the diagnosis of diabetes.

SPECIALIZED EVALUATION AND TESTING

The implicit goal of specialized evaluations in medicine in general is to improve diagnostic accuracy and direct successful therapy based on the specific diagnosis. A similar principle applies to sexual medicine. However, at the present time, despite the availability of various technologies that may specify and define the causation for ED (i.e., vasculogenic, neurogenic, endocrinogenic, psychogenic), the treatment plan for this sexual dysfunction can often be formulated without performing extensive diagnostic testing. Nonetheless,

such testing is frequently applied for diagnostic precision, typically by specialists, particularly in settings of complex clinical presentations. Table 27-5 summarizes the most frequently used evidence-based test procedures for diagnostic evaluations of ED (Rosen et al, 2004d).

Vascular Evaluation

The vascular evaluation for ED conceptually connotes surveying the vascular requirements of the sexual organ for the erectile response: arterial blood inflow, blood engorgement, and blood retention within the corporeal structures. From a diagnostic standpoint, the

TABLE 27-5 Evidence-Based Tests for Organic Erectile Dysfunction and Recommendations

Clinical evaluation and symptom scales: sexual dysfunction assessment in men. In: Lue TF, Basson R, Rosen F, et al, editors. *Sexual medicine: sexual dysfunctions in men and women*. Paris: Health Publications; 2004. p. 173-220.

studies aim to assist in deriving the classic diagnoses of arterial impairment and veno-occlusive dysfunction. As for all diagnostic testing, hemodynamic tests of the penis require patient counseling regarding the purpose, alternatives, risks, and benefits of any procedure before its implementation.

Combined Intracavernosal Injection and Stimulation

The combined intracavernosal injection and stimulation (CIS) test serves as a first-line evaluation of penile blood flow because of its very basic manner of administration and assessment. The test involves the intracavernosal injection of a vasodilatory drug or drugs as a direct pharmacologic stimulus, combined with genital or audiovisual sexual stimulation, and the erectile response is observed and rated by an independent assessor (Donatucci and Lue, 1992; Katlowitz et al, 1993). The test is designed to bypass neurologic and hormonal influences involved in the erectile response and allows the clinician to evaluate the vascular status of the penis directly and objectively.

The clinician may decide the protocol for using vasodilator drugs. Alternative regimens include alprostadil alone (Caverject or Edex, 10 to 20 µg), a combination of papaverine and phentolamine (Bimix, 0.3 mL), or a mixture of all three of these agents (Trimix, 0.3 mL). The procedure requires a syringe with a 5/8-inch needle (27 to 29 gauge), which is inserted at the lateral base of the penis directly into the corpus cavernosum for medication delivery. After needle withdrawal, manual compression is applied to the injection site for 5 minutes to prevent local hematoma formation. The assessment is done periodically subsequently with rating of both rigidity and duration of response. Repeated dosing may be performed if the initial erectile response is poor. Return to penile flaccidity is required before allowing the patient to leave the office, and if detumescence does not occur spontaneously in approximately an hour after dosing, intracavernosal injection of a diluted phenylephrine solution (500 µg/mL) can be administered every 3 to 5 minutes until flaccidity returns.

A normal CIS test, based on the assessment of a sustainably rigid erection, is understood to signify normal erectile hemodynamics. Alternative diagnoses of psychogenic, neurogenic, or endocrinogenic ED may then be considered. However, it is known that false-positive results might occur in as many as 20% of patients with borderline arterial inflow (as defined by the measurement of 25 to 35 cm/s peak cavernous artery systolic flow on duplex ultrasonography) (Pescatori et al, 1994). False-negative results are also possible and occur most commonly because of patient anxiety, needle phobia, or inadequate dosage.

Duplex Ultrasonography (Gray Scale or Color-Coded)

Duplex ultrasound of the penis following pharmacostimulation or CIS represents second-line evaluation of penile blood flow. However, it is the most reliable and least invasive diagnostic modality for assessing ED. The test adds an imaging dimension and a quantification component to the evaluation of blood flow in the penis distinct from first-line evaluation, which relies on the assessor's judgment alone.

The technique consists of high-resolution (7.5 to 12 MHz) real-time ultrasonography and color-pulsed Doppler, which serves to visualize the dorsal and cavernous arteries selectively and to perform hemodynamic blood-flow analysis (Lue et al, 1989; Sikka et al, 2013). Scanning is applied to the surface of the penis and may include the entire penis from the crura in the perineum to the tip. Color-coded duplex ultrasonography indicates the direction of blood flow within vessels, with red designating direction toward the probe and blue designating direction away from the probe (Broderrick and Arger, 1993; Herbener et al, 1994). Flow velocities are measured at baseline before injection and commonly every 5 minutes afterward up to 20 minutes. Cavernous arterial diameters may also be measured. Vascular anatomic communications between the paired cavernous arteries or between the dorsal and cavernous arteries should be noted (Fig. 27-4). Erection quality should also

Figure 27-4. Collateral circulation connecting the right dorsal artery (RDA) to the right cavernous artery (RCA), and the left cavernous artery (LCA) is shown by color duplex ultrasonography in a longitudinal view.

be simultaneously assessed and rated. An observed poor erection, possibly associated with patient anxiety, should prompt vasodilator redosing as recommended for the CIS test.

A standard pattern of Doppler waveforms occurs with hemodynamic changes in corporeal pressure during progression to normal full erection (Fig. 27-5) (Schwartz et al, 1991). In the filling phase when sinusoidal resistance is low (within 5 minutes after vasodilator injection), the waveform increases in size consistent with high forward flow during both systole and diastole. As intracavernous pressure increases, diastolic velocities decrease. With full erection, the systolic waveforms sharply peak and may be slightly less than during full tumescence. At maximal rigidity, when intracavernous pressure exceeds systemic diastolic blood pressure, diastolic flow may be zero. The sonographic color pattern of the cavernous artery may demonstrate an impressive shift from red to blue in association with the reversal of diastolic flow.

Normative values have been described for peak systolic velocity (PSV) and diameter of the cavernous arteries during increases in arterial inflow to the penis. Early studies documented that the PSV of the cavernous arteries consistently exceeded 25 cm/s within 5 minutes of vasodilator injection in patients with nonarteriogenic causes of ED (i.e., psychogenic, neurogenic) (Lue et al, 1985; Mueller and Lue, 1988). Investigators subsequently confirmed mean PSV of cavernous arteries after pharmacostimulation to range from 35 cm/s to 47 cm/s in normal subjects (Benson and Vickers, 1989; Shabsigh et al, 1990). A cut point at 25 cm/s included a sensitivity of 100% and a specificity of 95% in patients with abnormal pudendal arteriography (Quam et al, 1989). Diameter changes of the cavernous artery after vasodilator injection were found to increase less than 75% and rarely to exceed 0.7 mm in patients with severe vascular ED (Lue and Tanagho, 1987; Mueller and Lue, 1988). Importantly, unlike PSV changes, a percentage of cavernous arterial vasodilation was not found to correlate well with findings on pudendal arteriography (Jarow et al, 1993).

Figure 27-5. Artist's conception of the changes in diameter and flow waveform in the cavernous arteries induced by intracavernous injection of prostaglandin E₁ in a potent young man as demonstrated by duplex ultrasound. Forceful concentric pulsations are particularly noticeable during full erection.

Vascular arterial anatomic variants may confound the interpretation of duplex ultrasonography (Breza et al, 1989; Jarow et al, 1993). Early cavernous arterial branching or the presence of multiple such branches may affect blood-flow velocity determinations of the main cavernous artery. The presence of distal arterial perforators extending from the dorsal or spongiosal arteries also may alter the measurement of cavernous arterial blood-flow velocity. Accordingly, the clinician must recognize these variants to avoid making the incorrect diagnosis of arteriogenic ED. On the other hand, asymmetrical blood flow of the cavernous arteries may have diagnostic significance. The findings of dissimilar cavernous artery velocity measurements, which are greater than 10 cm/s between sides, or reversal of flow across a collateral may suggest a significant atherosclerotic lesion (Benson et al, 1993).

Duplex ultrasound measurements are informative for diagnosing vasculogenic ED (Rosen et al, 2004d). Cavernous arterial insufficiency is suggested when PSV is less than 25 cm/s; a PSV consistently greater than 35 cm/s defines normal cavernous arterial inflow. Cavernous artery acceleration time (i.e., PSV divided by systolic rise time) greater than 122 ms may also indicate this diagnosis. Cavernous veno-occlusive dysfunction, which refers to failure of erection maintenance despite adequate cavernous arterial inflow, is suggested by assorted sonographic parameters. Generally meaningful at 15 to 20 minutes after stimulatory onset, these parameters include persistent high systolic flow velocities (i.e., PSV >25 cm/s) and high end-diastolic flow velocities (EDV >5 cm/s), accompanied by rapid detumescence, following stimulatory onset. In addition, vascular resistive index (RI), based on the formula written as RI equals PSV minus EDV, which is then divided by PSV, has had tremendous diagnostic usefulness in this regard. The parameter is based on the concept that, as penile intracavernous pressure during erection achievement equals or exceeds diastolic pressure, diastolic flow in the corporeal bodies will approach zero and the value for RI will approach one. An RI greater than 0.9 has been associated with normal penile vascular function, and that less than 0.75 is consistent with veno-occlusive dysfunction (Naroda et al, 1996).

Several technical modifications of sonographic evaluation of the penis have been described. A portable Midus-pulsed Doppler unit connected to a laptop computer for in-office testing reliably records the Doppler waveform of the cavernous arteries despite the lack of a real-time ultrasound image (Metro and Broderick, 1999). Power Doppler offers an even more specialized technique to visualize distal ramifications of the main cavernous artery down to the level of arterioles (Sarteschi et al, 1998; Golubinski and Sikorski, 2002). A somewhat more invasive approach that evaluates the integrity of cavernous arterial flow involves the measurement of the cavernous artery systolic occlusion pressure (CASOP) by a Doppler transducer during saline intracavernosal infusion (Rhee et al, 1995). As a

variation on the stimulatory component of penile sonographic testing, a combination of an oral phosphodiesterase type 5 (PDE5) inhibitor in association with visual erotic stimulation has proven an effective, noninvasive method (Baçar et al, 2001; Speel et al, 2001). Sonographically measured postocclusive vasodilation of the cavernous arteries, which is believed to relate to the level of intact endothelial function in the penis, has been found diagnostic for organic ED (Virag et al, 2004). Cavernous artery intima-media thickness as demonstrated by high-resolution echo color Doppler ultrasound has been suggested as being more accurate than PSV in predicting vasculogenic ED (Caretta et al, 2009).

Dynamic Infusion Cavernosometry and Cavernosography

Cavernosometry and cavernosography, precisely referring to functional hemodynamic and radiographic assessments of the corpora cavernosa, represents third-line evaluation of the vascular integrity of the penis. The testing is indicated for select patients who are suspected of having a site-specific vasculogenic leak resulting from perineal or pelvic trauma or who have had lifelong ED (primary ED). When used, it generally precedes consideration for corrective penile vascular surgery.

The technique involves two needles inserted into the penis for simultaneous saline infusion and intracavernous pressure monitoring following intracavernosal pharmacologic injection (Glina and Ghanem, 2013). The testing requires complete trabecular smooth muscle relaxation to avoid erroneous results, and repeated and maximal pharmacologic dosing protocols are recommended (Hatzichristou et al, 1995). Measurements of maintenance flow rate, pressure drop, and CASOP are performed to verify complete smooth muscle relaxation (Fig. 27-6).

Dynamic infusion cavernosometry and cavernosography evaluates the penile venous outflow system. The existence of veno-occlusive dysfunction is indicated by the failure to increase intracavernous pressure to the level of the mean systolic blood pressure with saline infusion or the demonstration of a rapid drop of intracavernous pressure after cessation of saline infusion (Puyau and Lewis, 1983; Rudnick et al, 1991; Shabsigh et al, 1991; Motiwala, 1993). The flow rate required to maintain erection at an intracavernous pressure of more than 100 mm Hg is normally less than 3 to 5 mL/min, and the pressure decrease in 30 seconds from 150 mm Hg is normally less than 45 mm Hg. Cavernosography follows cavernosometric evaluation and is intended to show the site of venous leakage (Fig. 27-7). With normal veno-occlusive function, there should be opacification of the corpora cavernosa with minimal or no visualization of venous structures or corpus spongiosum. With impaired veno-occlusive function, leakage may be identified into such sites as the glans, corpus spongiosum, superficial dorsal veins, and cavernous and crural veins. More than one

site is visualized in the majority of patients (Lue et al, 1986; Rajfer et al, 1988; Shabsigh et al, 1991).

Penile Angiography

Penile angiography essentially refers to an anatomic study of the arterial vasculature of the penis and also represents third-line evaluation of the penile vascular system. It is commonly reserved for

the young patient with ED secondary to a traumatic arterial disruption or the patient with a history of penile compression injury, who is being considered for penile revascularization surgery (Sikka et al, 2013).

The procedure involves selective cannulation of the internal pudendal artery and injection of radiographic contrast. The intracavernosal injection of a vasodilating agent is optimally used to induce maximal vasodilation of the penile arterial supply. The anatomy and radiographic appearance of the iliac, internal pudendal, and penile arteries are then evaluated and documented (Fig. 27-8). The inferior epigastric arteries are frequently studied as well to determine their suitability for use in surgical revascularization. It should be recognized that significant variation of the intrapenile arterial anatomy exists, challenging the angiographer to differentiate congenital variations from acquired abnormalities and to establish their clinicopathologic relevance (Bähren et al, 1988; Benson et al, 1993).

Figure 27-6. This tracing depicts four simultaneous variables obtained during the third phase of dynamic infusion cavernosometry and cavernosography. *Top to bottom:* Cavernosal artery flow recorded by using a continuous-wave Doppler ultrasound probe; systemic brachial systolic and diastolic arterial blood pressure (150/87 mm Hg); intracavernosal pressure, which varied from 70 to 160 mm Hg in this tracing; and intracavernosal heparinized saline inflow. The intracavernosal pressure at which the cavernosal artery pulsations returned, which is the effective cavernosal artery systolic occlusion pressure (CASOP), was 108 mm Hg. The gradient between the brachial and the cavernosal artery systolic occlusion pressures was 150 to 108, or 42 mm Hg, which is abnormal.

Historical and Investigational Studies of Penile Blood Flow

Penile Brachial Pressure Index

The penile brachial pressure index (PBI) test refers to the penile systolic blood pressure divided by the brachial systolic blood pressure. The technique involves applying a small pediatric blood pressure cuff to the base of the flaccid penis and measuring the systolic blood pressure with a continuous-wave Doppler probe. A PBI of 0.7 or less has been used to indicate arteriogenic ED (Metz and Bengtsson, 1981). The technique has not been found valid because it does not assess the hemodynamic properties of a functionally relevant, induced erection, and thus it is not recommended for use (Aitchison et al, 1990; Mueller et al, 1990).

Penile Plethysmography (Penile Pulse Volume Recording)

This test evaluates arterial pressure waveforms in the penis with an aggregate of the contributions of all penile vessels (Kedia, 1983). It requires the application of a 2.5- or 3-cm cuff connected to an air plethysmograph applied to the base of the penis, inflating the cuff to a pressure greater than brachial systolic pressure, and then decreasing the pressure by 10-mm Hg increments while recording pressure waveform tracings. Abnormal pressure waveforms by diagnostic criteria have been used to indicate vasculogenic ED (Doyle and Yu, 1986). Because this study is performed in the flaccid penis, as is the PBI, its clinical relevance has been questioned. Despite this concern, a technical modification that measures postischemic flow-mediated dilation was introduced as being

Figure 27-7. Pharmacologic cavernosography. **A**, In a patient 1 year after a penile fracture, a communication between the corpus cavernosum and the spongiosum is seen. **B**, In a 27-year-old man with primary impotence, venous leakage from the crura is seen.

Figure 27-8. In this patient with a pelvic injury, pharmacologic penile arteriography (after intracavernous injection of 60 mg of papaverine) shows patent common penile, dorsal, and cavernous arteries (A) and nonvisualization of the common penile artery and its branches (B).

informative regarding penile vascular endothelial function (Dayan et al, 2005; Vardi et al, 2009).

Radioisotopic Penography

This test quantifies changes in penile blood volume after intracavernosal injection of a vasoactive agent using ^{99m}Tc -labeled red blood cells (Shirai et al, 1976). Extremely low flow is understood to mean arteriogenic ED (Smith et al, 1998). An evaluation comparing color duplex ultrasonography and radionuclide penography showed poor correlation (Glass et al, 1996).

Penile Magnetic Resonance Imaging

This test has significant potential applications for the assessment of anatomic details of the penis and penile microcirculation. Angiographic techniques may be combined with this test to evaluate the anatomic condition of the internal iliac and penile vasculature. Magnetic resonance angiography has been shown to correlate well with color duplex ultrasound testing (Stehling et al, 1997; John et al, 1999).

Penile Near Infrared Spectrophotometry

This test provides continuous, quantitative measurements of penile blood flow using a specialized near infrared spectrophotometry instrument (Burnett et al, 2000). It may be applied with an erectile stimulus and documents the hemodynamic phenomena of erection. Penile spectrophotometry has been further investigated in combination with intraurethral pharmacotherapy documenting blood-flow increase to the penis with this erectogenic modality (Padmanabhan and McCullough, 2007). Further investigation of this technique is needed to establish its clinical usefulness.

Cavernous Smooth Muscle Content

This test evaluates the smooth muscle composition of the corporeal tissue by light microscopic and computed morphometric assessment of biopsies of the penis and may serve adjunctively in the diagnosis of vasculogenic ED (Wespes et al, 1992). A reduced proportion of corporeal smooth muscle (and correspondingly increased collagen) has been observed in older men with veno-occlusive dysfunction (19% to 36% smooth muscle) and arteriogenic ED (10%

to 25%), compared with that of young, healthy men with normal erections and penile curvature (40% to 52%) (Wespes et al, 1991). In part because of its invasiveness, the test is controversial and thus it remains investigational at present.

Psychophysiologic Evaluation

The psychophysiologic evaluation of ED seeks to assess the erectile response by applying techniques that directly measure penile tumescence and rigidity. From the historical perspective of ED diagnostics, testing was applied primarily to differentiate psychogenic from organic ED. In general, the documentation of a full erection indicates functional integrity of the neurovascular axis regulating penile erection and thereby raises suspicion of a psychogenic etiology. There are several approaches to perform this evaluation. Importantly, the psychophysiologic evaluation does not currently represent first-line evaluation for ED, largely because of technical and cost limitations associated with current techniques. When considered to undergo any of these tests as part of a diagnostic plan, patients are counseled regarding the expected use, risks, and benefits of the tests.

Penile Tumescence and Rigidity Monitoring

Nocturnal penile tumescence (NPT) monitoring, which describes the study of erections that occur with nighttime sleep, was classically described as a technique offering the assessment of physiologic erectile ability (Wasserman et al, 1980). As a standard, sleep laboratory nocturnal penile tumescence and rigidity (NPTR) testing applies nocturnal monitoring devices that measure the number of episodes, tumescence (circumference change by strain gauges), maximal penile rigidity, and duration of nocturnal erections (Kessler, 1988). The conventional approach is to perform monitoring in conjunction with electroencephalography, electrooculography, and electromyography (EMG), with nasal airflow and oxygen saturation to document rapid eye movement (REM) sleep and the presence or absence of hypoxia (sleep apnea). It is important to note that documentation of REM sleep is undertaken because of the observation that true erectile phenomena occurring during sleep are associated with the REM sleep phase (Fisher et al, 1965). Sleep movement patterns are also monitored because periodic limb movement disorders are associated with abnormal NPT. Axial rigidity is measured along with photography of the erect penis when

awakening the patient at maximal tumescence; a buckling device is applied to the tip of the penis to measure resistance (500 g minimum for vaginal penetration, 1.5 kg suggestive of complete rigidity) (Karacan et al, 1977). NPT has traditionally been performed during 2 to 3 nights to overcome the so-called first-night effect when REM sleep is inconsistent. Formal testing, which involves a specially equipped sleep laboratory staffed with trained observers, is costly. The monitoring of diurnal penile tumescence, in reference to monitoring performed during daytime napping, has served alternatively as an in-office evaluation (Morales et al, 1994).

Rigiscan (Timm Medical Technologies, Inc., Minneapolis, MN) is an automated, portable device used for NPTR, which combines the monitoring of radial rigidity, tumescence, number, and duration of erectile events (Bradley et al, 1985). The device employs two loops, one placed at the base of the penis and the other placed at the coronal sulcus (respectively, base and tip recording sites), and these loops record penile tumescence (circumference) and radial rigidity with timed, standardized constrictions of the loops. A baseline initialization is performed with the patient in the office, and then it is calibrated for home use. At home, registrations of penile rigidity are done every 3 minutes and increased to every 30 seconds when the base loop detects a circumference increase of greater than 10 mm (Fig. 27-9). Recommended criteria for normal NPTR

include four to five erectile episodes per night, mean duration longer than 30 minutes, an increase in circumference of more than 3 cm at the base and more than 2 cm at the tip, and maximal rigidity greater than 70% at both base and tip (Cilurzo et al, 1992). A computerized program has yielded standardized data measurements according to cumulative distribution of time-intensity measures, defined as tumescence activity units (TAU) and radial rigidity activity units (RAU) (Burris et al, 1989; Levine and Carroll, 1994). Potential limitations of Rigiscan include the fact that radial rigidity does not accurately predict axial rigidity (Allen et al, 1993; Licht et al, 1995) and considerable variability apparently exists even in normal subjects (Levine and Carroll, 1994). Further, the manner of testing does not allow verification of the presence of REM sleep.

NPT electrobioimpedance (NEVA, American Medical Systems, Inc., Minnetonka, MN) is a device introduced more recently that assesses volumetric changes in the penis during nocturnal erections (Knoll and Abrams, 1999). The device consists of three small electrode pads applied to the hip and the penile base and glans and a small recording device attached to the patient's thigh. In operation, an undetectable alternating current is transmitted from the glans electrode to the hip ground, and the penile base electrode measures impedance and changes in penile length. Impedance measures decrease in concert with increases in cross-sectional area of the penis during nocturnal tumescence. Further investigation is needed to establish the relationship of volumetric changes and the rigidity of the penis. Similar to Rigiscan, the technique also does not include REM sleep monitoring and correlations.

In summary, NPTR monitoring is an attractive approach for objectively evaluating the somatic basis of erectile ability, theoretically devoid of psychological interference. However, it has several apparent shortcomings, which limit its routine use for diagnostic purposes (Jannini et al, 2009). Central issues are that the testing does not indicate the cause and severity of ED and that the results may be poorly reproducible. Another fundamental issue is whether the testing appropriately evaluates wakeful, sexually relevant erections. Indeed, erections observed during NPTR monitoring do not unequivocally equate with erections sufficient for sexual performance, and false-positive results are possible for various clinical situations (e.g., multiple sclerosis). False-negative results may occur in aging patients and in patients with depression or anxiety, which may conditionally affect the physiology of sleep-related erectile phenomena. Nonetheless, NPTR monitoring may be considered in special circumstances such as when the cause of ED is obscure and noninvasive testing is desirable.

Audiovisual and Vibratory Stimulation

Alternative erectogenic methods can be used in conjunction with diagnostic testing of erectile function. Erotic stimulation by explicit videotape material with monitoring has been used as a reliable as well as a time- and cost-effective alternative to NPTR for differentiating between organic and psychogenic ED presentations (Sakheim et al, 1987; Bancroft et al, 1991). It is also considered more physiologic, consistent with erectile behavior when awake. The testing has potential limitations, with possible false-negative responses occurring in the presence of endocrine abnormalities (Carani et al, 1992; Greenstein et al, 1995) and false-positive responses occurring in psychological situations such as erotic excitement inhibition (Chung and Choi, 1990). As one may infer, these methods can be applied in conjunction with other stimulatory conditions (e.g., pharmacologic erection testing) as well as erectile function assessment approaches (e.g., Rigiscan monitoring) (Katlowitz et al, 1993; Martins and Reis, 1997).

Neuroimaging

Diagnostic techniques to evaluate central mechanisms of male sexual arousal have contributed to the psychophysiologic investigation of ED. Positron emission tomography (Miyagawa et al, 2007) and functional magnetic resonance imaging (Park et al, 2001;

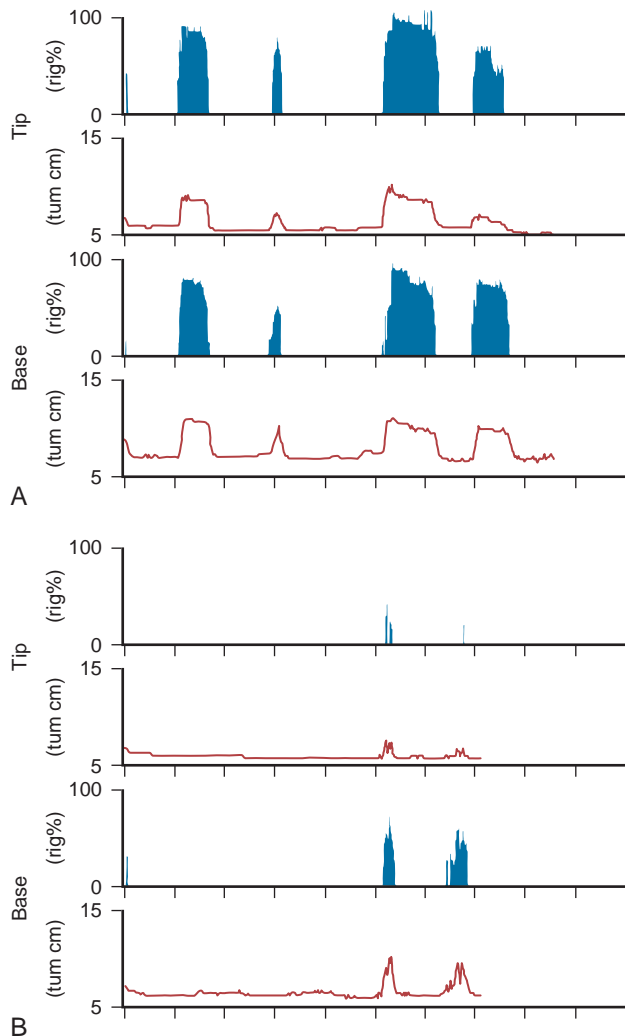

Figure 27-9. The RigiScan device has been designed to measure penile rigidity during home nocturnal monitoring. **A**, A study in a patient with at least two episodes of well-sustained, completely rigid nocturnal erections. **B**, A study with two episodes of poorly sustained, poorly rigid nocturnal erections. Such home studies fail to document sleep quality.

Montorsi et al, 2003; Mouras et al, 2003; Ferretti et al, 2005) have been used in association with video sexual stimulation or an erectogenic pharmacologic stimulus (e.g., oral apomorphine). Studies have documented key brain regions associated with sexual arousal that induce penile erection (i.e., anterior cingulate, insula, amygdala, hypothalamus, and secondary somatosensory cortices). Interestingly, functional abnormalities in the brain have been shown in patients with psychogenic ED, suggesting that this diagnosis may be attributable to an actual biologic basis. More investigation in this area is necessary before determining its clinical role.

Psychological Evaluation

The psychological evaluation of ED addresses psychogenic contributions to clinical presentations, essentially psychological and interpersonal factors interfering with erectile function. These aspects should not be underestimated, and it is well documented in population studies that ED is associated with anxiety, depression, low degrees of self-esteem, negative outlook on life, self-reported emotional stress, and a history of sexual coercion (Feldman et al, 1994; Laumann et al, 2007). The urologist's role in initiating a psychological evaluation is not necessarily complicated, and a basic attempt to use queries about a patient's psychological health is helpful in assessing sexual health (Rowland et al, 2005).

The diagnostic interview is central to the psychological evaluation, and this process should be straightforwardly handled. Readily discernible causes of sexual dysfunction may be elicited, such as fear of failure, performance anxiety (for widowers, this may include complex interactions of dating, new partners, and unresolved mourning/guilt), insufficient sexual stimulation, loss of attraction for the partner, adjustment to a chronic illness or surgery, and relationship conflicts. In addition, causes that are less immediately discernible may be identified to include unresolved parental attachments, sexual identity issues, history of sexual trauma, occurrence of extramarital affairs, and cultural-religious taboos (Leach and Bethune, 1996; Laumann et al, 2007).

The interviewer should be mindful of the possibility of a primary psychogenic ED presentation (Turnbull and Weinberg, 1983). In the absence of organic risk factors, a primary psychogenic ED causation may be suspected. Further support for the diagnosis may follow the confirmation of noncoital erections (i.e., masturbatory, nocturnal, or when awakening). Clinical subtypes of psychogenic ED may be further identified: (1) generalized versus situational, and (2) lifelong (primary) versus acquired (secondary, including substance abuse or major psychiatric illness).

The interviewer should also inquire about relationship factors (Rosen, 2001). Relationship conflicts may be the source of psychogenic ED or otherwise may exacerbate organic ED. A couple's issues include intimacy and trust, status and dominance, loss of sexual attraction, ability to achieve sexual satisfaction without erection, and communication problems. Important information may derive not just from interviewing the patient alone, and interviews both with the couple together and of partners separately may provide insight.

Complex intrapsychic causes of sexual dysfunction are often relevant for the ED presentation and may become evident during the diagnostic interview. The clinical history may show a significant traumatic life experience, cultural or religious strife, compulsive sexual behavior, or neurotic process. It may suggest the presence of serious psychiatric comorbidities such as substance abuse, depressive symptoms, anxiety disorder, or personality disorder. It is recognized that the urologist may not have the professional background, comfort, or time to address these issues definitively, and a referral to a psychological expert for further attention would certainly be appropriate.

Neurologic Evaluation

The neurologic evaluation of ED is concerned with neurogenic associations with ED presentations. The importance of testing for deficits in the neurologic system relates to the principal regulatory

role of this system for governing erectile function. Target sites for evaluation include peripheral, spinal, and supraspinal centers as well as both somatic and autonomic pathways involved in this biologic response. In line with this purpose, several diagnostic tests have been introduced. However, thus far they have had limited impact on routine clinical management decisions, and much of the available testing in this realm is reserved for research protocols and medicolegal investigations (Giuliano and Rowland, 2013). Additionally, fundamental problems surround the lack of sensitivity, reproducibility, reliability, and validity for many of these tests. This concern is particularly so for autonomic function tests, distinct from somatic function testing, which has been shown to be reproducible and valid. Otherwise, tests that could be most useful for evaluating penile erection, for example, neurotransmitter release, are altogether undeveloped.

Somatic Nervous System

Biothesiometry. This test represents a technique to assess afferent sensory function of the penis (Padma-Nathan, 1988). Testing involves a handheld electromagnetic device placed on the pulp of the index fingers, both sides of the penile shaft, and the glans penis. Measurements of sensory perception threshold are obtained in response to various amplitudes of vibratory stimulation. Investigators have questioned the usefulness of penile glans biothesiometry, which does not accurately portray neurophysiologic function of the dorsal penile nerve because of limitations in recording responses to vibratory stimuli of glanular skin (Bemelmans et al, 1995).

Sacral Evoked Response: Bulbocavernosus Reflex Latency. This test is used to assess the somatosensory reflexogenic mechanism of penile erection. Testing consists of a direct-current stimulator, which delivers square-wave impulses via two stimulating ring electrodes placed around the penis, one secured near the corona and the other secured 3 cm more proximally, and a recorder that gauges responses via concentric needle electrodes placed in the right and left bulbocavernosus muscles. Latency period is measured as the interval from the beginning of each stimulus to the beginning of each response. An abnormal latency time, defined as a value more than three standard deviations above the mean (30 to 40 ms), indicates a high probability of neuropathology (Padma-Nathan, 1988). However, the use of this test has been questioned, and it has been shown that a full battery of electrophysiologic tests evaluating limb nerve function is more sensitive in diagnosing neuropathy than such tests specific to pudendal nerve function alone (Vodusek et al, 1993; Ho et al, 1996).

Dorsal Nerve Conduction Velocity. This test in concept extends from pudendal nerve function reflex testing and involves electrophysiologic stimulation with two stimulating electrodes placed at the glans and the base of the penis for obtaining two bulbocavernosus reflex latency measurements. Conduction velocity of the dorsal nerve is represented by dividing the distance between the two stimulating electrodes by the difference in latency times recorded from both sites. An average conduction velocity of 23.5 m/s with a range of 21.4 to 29.1 m/s is found in normal subjects (Gerstenberg and Bradley, 1983). Abnormal nerve conduction velocities were found to be diagnostic for neurogenic ED in patients with diabetes (Kaneko and Bradley, 1987).

Genitocerebral Evoked Potential. This test is designed to assess afferent sensory mechanisms and stimulus processing at spinal and supraspinal nervous system levels. The testing requires complex electronic equipment for recording the evoked potential waveforms overlying the sacral spinal cord and cerebral cortex in response to dorsal penile nerve electrical stimulation (Spudis et al, 1989). Central conduction time is recorded as the difference between the latency times after stimulation of the first replicated spinal response and the first replicated cerebral response (Padma-Nathan, 1988). The test has been questioned as having poor discriminatory value of response latencies (Pickard et al, 1994). However, it may still serve as an objective tool to define characteristics of afferent penile sensory dysfunction in patients with subtle abnormalities on neurologic examination.

Autonomic Nervous System

Heart Rate Variability and Sympathetic Skin Response. The test of heart rate control (mainly parasympathetic) consists of measuring heart rate variations during quiet breathing, deep breathing, and in response to raising the feet. Normative parameters have been documented. The test of sympathetic skin response involves producing an electrical shock stimulus at a certain location, for example, median or tibial nerve, and recording the evoked potential elsewhere, for example, contralateral hand or foot or penis. Recording from the penis is considered to be a potentially useful method of testing penile autonomic innervation (Daffertshofer et al, 1994).

Penile Thermal Sensory Testing. This test serves to assess the conductance of small sensory nerve fibers, which are affected by autonomic disturbances consistent with neuropathy. The testing measures thermal threshold. In studies of the penis, it seems to correlate well with the clinical determination of neurogenic ED (Lefaucheur et al, 2001; Bleustein et al, 2003).

Corpus Cavernosum Electromyography and Single Potential Analysis of Cavernous Electrical Activity. This test offers a direct recording of cavernous electrical activity, which varies between penile flaccidity and tumescence (Wagner et al, 1989; Leddy et al, 2012). In the normally flaccid penis, electrical activity is described as exhibiting a rhythmic slow wave with intermittent bursts of activity. As penile tumescence occurs (such as in response to visual sexual stimulation or after intracavernosal injection of a smooth muscle relaxant), this activity ceases. During detumescence, the baseline electrical activity returns. Patients with suspected autonomic neuropathy were demonstrated to display a discordant pattern, having continued electrical activity during erectogenic stimuli (Wagner et al, 1989). Recording techniques have been standardized, and normative values have been defined to include maximum peak-to-peak amplitudes between 120 and 500 mV and mean potential durations of 12 seconds (Stief et al, 1994). However, the clinical utility of this test remains in question (Kellner et al, 2000; Jiang et al, 2003).

Hormonal Evaluation

The hormonal evaluation for ED explores an endocrinologic basis for the sexual dysfunction and recognizes accumulating evidence that endocrinopathies potentially impact the physiology of penile erection (Traish and Guay, 2006; Mironi et al, 2009). Several endocrine conditions are particularly relevant in this regard: hypogonadism (decrease or absence of hormonal secretion from the gonads), hyperthyroidism (excessive thyroid hormone release), and diabetes (altered modulation of androgen function (Wang et al, 2011; Maggi et al, 2013)). The diagnostic evaluation may be undertaken in view of their possible influences on erectile function. The clinical history may raise suspicion regarding the diagnosis, although the clinical presentation of an endocrinopathy may be variable. Several questionnaires have been proposed for use in screening, particularly with respect to hypogonadism (Morley et al, 2000; Daig et al, 2003; Heinemann, 2005). A new psychometrically validated hypogonadism screener has been developed to identify men with symptoms of hypogonadism (Rosen et al, 2011). However, their general lack of specificity for most presentations and the lack of sensitivity for some others has limited their widespread applications (Morales et al, 2007). The central feature of this evaluation involves biochemical testing for serum hormonal levels (Bhasin et al, 2010).

Serum Testosterone Measurements

Much focus in assessing the impact of endocrinopathies on male sexual function has centered on the role of androgens. Androgen deficiency or low testosterone levels are observed in as few as 2% and as many as 33% of men presenting clinically with ED (Korenman et al, 1990; Citron et al, 1996; Soran and Wu, 2005). Differences in patient populations under study likely account for the variation in statistics. In acknowledging that aging may represent

the primary cause of declining androgens, thought leaders have variously applied such terms as androgen deficiency of the aging male (ADAM), partial androgen deficiency of the aging male (PADAM), hypoandrogenism, symptomatic late-onset hypogonadism (SLOH), and andropause to designate this association.

It is important to understand the biology of testosterone production and function so as to proceed with its evaluation in laboratory. Testosterone circulates in three fractions: free (0.5% to 3%), tightly bound to sex hormone-binding globulin (SHBG) (~30%), and loosely bound to albumin and other serum proteins (~67%) (Basaria and Dobs, 2001; Freeman et al, 2001). Free testosterone and albumin-bound portions comprise the bioavailable testosterone fraction. The relative concentrations of the carrier proteins (SHBG and albumin) serve to modulate androgen function. Numerous conditions can alter the SHBG fraction and accordingly affect bioavailable testosterone to some extent even if the total testosterone measurement is unchanged (Bhasin et al, 2010). Decreased SHBG is associated with moderate obesity, nephrotic syndrome, hypothyroidism, and the use of glucocorticoids, progestins, and androgenic steroids, and it produces an elevation in bioavailable testosterone. Increased SHBG is associated with aging, hepatic cirrhosis, hyperthyroidism, human immunodeficiency virus infection, and the use of anticonvulsants and estrogens, and it produces a lowering in bioavailable testosterone. Despite the observation that lower levels of SHBG are associated with insulin resistance (Stellato et al, 2000), variable SHBG levels have been documented in diabetic men, possibly because of confounding obesity and aging factors, and the diagnosis of hypogonadism in this population should rely on the measurement of a low bioavailable testosterone level (see later) (Kapoor et al, 2007).

Theoretically, the unbound or free fraction measurement of testosterone offers the most relevant determination of testosterone bioavailability. However, commercial assays for free testosterone are known to be inconsistent and have been considered as invalid by some investigators (Vermeulen et al, 1999; Ly et al, 2010; Field and Wheeler, 2013). The best indicator of androgen status is the calculated bioavailable testosterone (free testosterone and albumin-bound testosterone). A formula for this calculation is found on the website of the International Society for the Study of the Aging Male at <http://www.issam.ch/freetesto.htm>, and this formula requires entries for the values of total testosterone and SHBG. In men with serious liver disease or hypoalbuminemia, entry of the serum albumin value may be useful for obtaining the best calculation.

For screening purposes, measurement of total serum testosterone level is generally sufficient. It is recommended that the blood draw be performed between 7:00 AM and 11:00 AM when there is a peak serum testosterone level, accounting for the fact that diurnal variation occurs in younger and middle-aged men (Wang et al, 2009). The typical reference range for the total testosterone measurement is 280 to 1000 ng/dL. Because of individual variability, it is recognized that the normal range for testosterone beyond which replacement therapy should be initiated remains unresolved. If the testosterone level is below or at the low limit of normal, blood draw should be repeated for confirmation. On the other hand, a mildly abnormal testosterone level might be found to be normal in 30% of patients on repeat testing (Bhasin et al, 2010). The clinical scenario, such as the presence of conditions that alter testosterone carrier proteins, may prompt further testing and assessment decisions.

Serum Gonadotropin Measurements

When proceeding with a second total testosterone determination, assessment of LH and prolactin should also be included. Measurement of serum gonadotropins will help to localize the source of the hypogonadism. It is understood that testosterone release involves the integrative activity of the hypothalamic-pituitary-gonadal axis and its regulatory feedback mechanisms, and disruption at any level of this axis may account for hypogonadism (Bhasin et al, 2010). A result of low testosterone is decreased

negative feedback to the hypothalamus and pituitary, causing increased secretion of LH and follicle-stimulating hormone (FSH). Elevated serum LH and FSH releases are appropriate pituitary responses to low serum testosterone levels, which is consistent with testicular failure (primary hypogonadism). In contrast, normal or low serum LH and FSH releases in the setting of low serum testosterone levels indicate an inappropriate response and suggest a central disorder (secondary hypogonadism).

Serum Prolactin Measurement

Hyperprolactinemia causes hypogonadism by suppression of gonadotropin-releasing hormone from the hypothalamus, which impairs the pulsatile LH secretion required for serum testosterone production by the gonads (Morales et al, 2004). An additional possible mechanism for sexual dysfunction, specifically loss of sexual libido, in patients with hyperprolactinemia independent of the circulating level of testosterone relates to an interference of the peripheral conversion of testosterone to dihydrotestosterone (DHT) (Lobo and Kletzky, 1983). Suspicion of hyperprolactinemia is raised in the patient with low serum testosterone and low or inappropriately normal LH. However, controversy surrounds the consideration of routine determinations of prolactin in men with ED, with some indicating the low yield in doing so (Johnson and Jarow, 1992; Govier et al, 1996) and others finding that low serum testosterone or low sexual desire does not always coincide with the diagnosis (Buvat and Lemaire, 1997; Johri et al, 2001). Causes of the condition include various medications such as antipsychotic agents, tricyclic depressants and opiates, prolactin-secreting tumors, hypothyroidism, hypothalamic lesions, renal insufficiency, cirrhosis, and chest wall lesions (Zeitlin and Rajfer, 2000; Molitch, 2005).

Magnetic Resonance Imaging Scans

Cases of central (hypogonadotropic) hypogonadism as well as unexplained hyperprolactinemia prompt central imaging of the pituitary. This evaluation commonly involves magnetic resonance imaging, which can identify structural abnormalities (Citron et al, 1996; Petak et al, 2002; Rhoden et al, 2003). Generally accepted guidelines provide indications for pituitary imaging: cases of severe central hypogonadism (testosterone <150 ng/dL) and suspicion of pituitary disease (i.e., panhypopituitarism, persistent hyperprolactinemia, or symptoms of tumor mass effect).

Serum Thyroid Function Tests

Hyperthyroidism is associated with ED, possibly by increasing aromatization of testosterone into estrogen (which raises levels of SHBG) (Morales et al, 2004) or by increasing adrenergic tone (which causes smooth muscle contractile effects or exerts psychobehavioral effects) (Carani et al, 2005). Symptoms of hyperthyroidism, such as hyperactivity, irritability, heat intolerance, palpitations, fatigue, and weight loss, are often reported, and physical signs such as tachycardia, tremor, goiter, and eyelid retraction are often identified. The diagnosis is made biochemically by measurement of high levels of thyroid hormone (total or free thyroxine [T₄] or triiodothyronine [T₃]) with a low-serum thyroid-stimulating hormone level.

TREATMENT CONSIDERATIONS

The treatment of ED axiomatically follows an appropriate diagnostic workup. Although current interventions are both etiologically specific and nonspecific, an intervention that is specific for the cause of ED ideally offers the opportunity to treat ED with a corrective purpose in mind. Current recommendations adhere to a patient goal-directed focus to therapy and specify that therapeutic options are presented according to a step-care clinical

KEY POINTS: DIAGNOSTIC EVALUATION

- The basic evaluation of ED consists of a detailed case history, physical examination, and proper laboratory tests.
- The sexual history should define the characteristics of the ED presentation according to such features as its onset, duration, conditions, severity, and etiology.
- Cardiac risk assessment and risk reduction interventions are appropriate when necessary for all patients presenting for ED evaluations.
- The hormonal evaluation for ED explores an endocrinologic basis for the disorder, with special consideration given to hypogonadism, hyperthyroidism, and diabetes as possible influences.
- Questionnaires and other patient self-report measures offer practical help in documenting the presence, severity, and responsiveness to treatment of ED.
- Specialized evaluation and testing may be required for individuals with complicated or atypical presentations of ED, and they potentially offer improved therapeutic outcomes for these presentations.

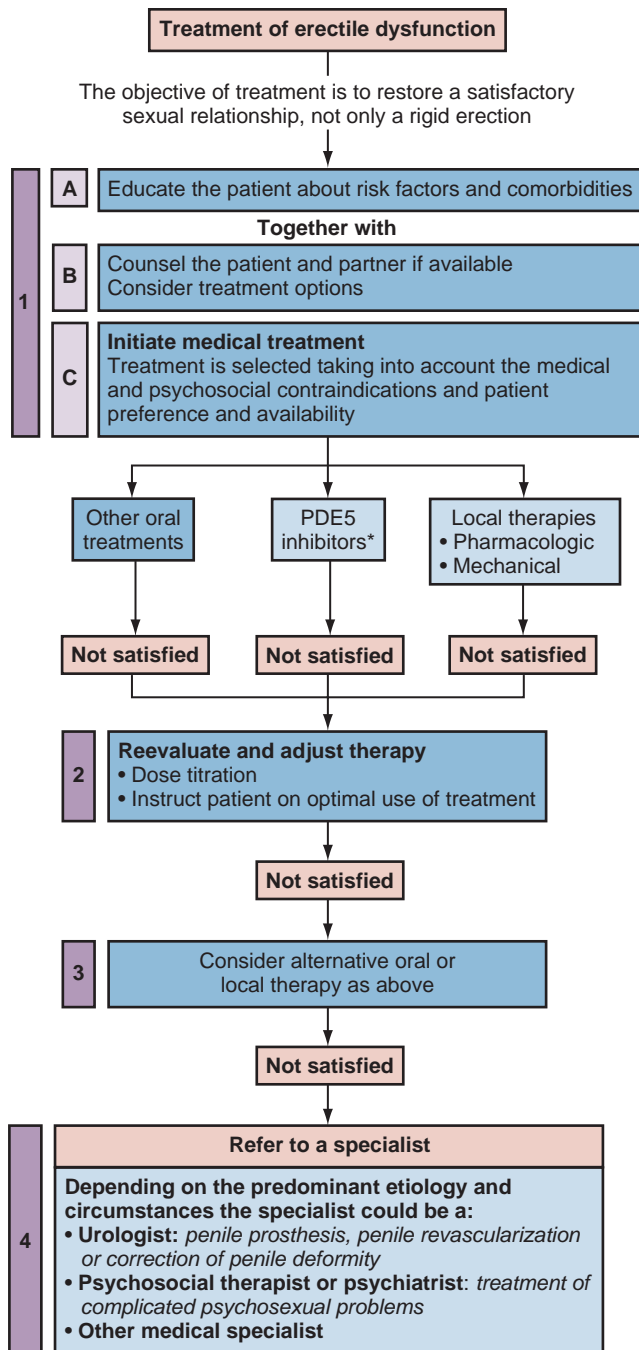

management approach (Fig. 27-10) (Montague et al, 2005; Hatzichristou et al, 2010).

Lifestyle Modification

The risk of developing ED is significantly associated with the presence of comorbid health conditions such as diabetes, cardiovascular disease, and metabolic syndromes that are either preventable or to a minimal extent treatable in endeavoring to optimize health status (Kostis et al, 2005). It stands to reason that optimization of these diseases offers opportunities to prevent the development of ED or to ameliorate its extent (Glina et al, 2013).

Epidemiologic studies have shown examinations of potentially modifiable risk factors and in some instances have provided support that risk modification may indeed improve erectile function. For instance, several reports have suggested that the discontinuation of cigarette smoking results in a recovery of functional erection status (Mannino et al, 1994; Feldman et al, 2000; Bacon et al, 2006). A beneficial role of increasing exercise for those with a sedentary lifestyle in men with ED was also evident (Feldman et al, 1994; Derby et al, 2000). In a prospective study, obese men with moderate ED and no overt symptoms of cardiovascular disease showed significant improvements in IIEF scores after exercise and weight control when compared with a control group that followed an educational program alone (Esposito et al, 2004). Significant changes in body mass index, C-reactive protein, and physical activity scores were observed in the intervention group compared with the control group. Mediterranean-style diets and a reduction in caloric intake have been found to improve erectile function in men with metabolic syndrome (Esposito et al, 2006). A change to a no-nose saddle from a conventional saddle was shown to recover erectile function, presumably by alleviating perineal trauma, in a short-term interventional study of men with ED associated with occupational bicycle riding (Schrader et al, 2008).

Reports indicating that ED is potentially ameliorated by lifestyle modifications of risk factors that predispose this sexual dysfunction are most illuminative. The role of lifestyle modifications to prevent or to treat ED has gained support by way of systematic reviews and meta-analysis (Kupelian et al, 2010; Gupta et al, 2011; Porst et al, 2013). The mechanisms of this effect may include reduced cardiovascular risk factors, increased serum testosterone levels, and overall improved mood and self-esteem (Gupta et al, 2011; Meldrum et al, 2012; Glina et al, 2013). Ongoing clinical and basic science investigation may further affirm the benefits of lifestyle modification and clarify its mechanistic basis.

*PDE5 inhibitors are the preferred treatment option in the large majority of patients.

Figure 27-10. Treatment algorithm for erectile dysfunction recommended by the International Consultations on Sexual Medicine. PDE5, phosphodiesterase type 5.

Medication Change

It is possible that a certain medication is an offending factor resulting in the clinical presentation of ED. After this inference is made, an appropriate next step would be to change to a different dose or type of medication entirely, considering that this action may reverse ED in some patients (Ralph and McNicholas, 2000). For instance, switching antihypertensive therapies from thiazide diuretics and β -blockers to calcium channel blockers and renin-angiotensin system inhibitors (i.e., angiotensin-converting enzyme inhibitors and angiotensin receptor blockers) may recover erectile function in men developing ED in this clinical setting.

Similarly, in patients suffering adverse sexual dysfunction effects from the use of SSRIs (e.g., ED, retarded ejaculation), treatment strategies such as drug substitution (e.g., bupropion, nefazodone, buspirone, mirtazapine), drug holidays, SSRI dosage reduction, watchful waiting, and administration of PDE5 inhibitors have enabled sexual function recovery (Rosen et al, 1999b; Nurnberg et al, 2001).

Psychosexual Therapy

Because of the frequent interplay of psychological and interpersonal factors in clinical presentations of ED, it is hardly surprising to consider that psychosexual therapy should be included in the therapeutic armamentarium for this sexual dysfunction. A strong limitation in this area is that evidence-based investigation and well-controlled, large-scale outcome research that documents the efficacy of interventions are generally lacking. In practice, psychosexual therapy does represent an ill-defined combination of interventions and interpretations, based on behavioral, relational, psychoanalytic, and cognitive psychology concepts. A variety of interventions are used: systematic anxiety reduction/desensitization, sensate focus, interpersonal therapy, cognitive-behavior therapy, sex education, couples' communication and sexual skills training, and masturbation exercises (Althof et al, 2005). Integrated treatments, which combine psychosexual interventions with medical therapies such as oral therapy, intracavernosal injection, or vacuum device therapy, have also proved successful in managing ED presentations, particularly those associated with motivational obstacles (Hawton, 1998; Althof et al, 2005). It is understandable that the common urologist may not feel comfortable or does not possess the necessary training to address complicated psychosocial concerns. However, for mild to moderate psychosocial matters, the urologist may be prepared to proceed with a "biopsychosocial" model that minimally involves awareness of psychosocial issues and preparedness to counsel a patient or couple about normal sexual function and acceptable sexual behaviors (Althof and Needle, 2011). Collaborative efforts with a mental health clinician who has expertise in psychosexual therapy may be necessary to implement intensive therapy techniques.

Hormonal Therapy

A prescription of hormonal therapy is considered so as to impact the clinical presentation of ED for the patient in whom a hormonal disturbance is identified. The urologist's role is fitting for the treatment of primary hypogonadism and hyperprolactinemia, whereas endocrinologists would be considered as the foremost consultants for other endocrinopathies.

Testosterone Replacement

Androgen replacement addresses straightforwardly the clinical complaint that is associated with hypogonadism. As a general principle of sex steroid replacement therapy, serum hormone levels to be achieved daily throughout 24 hours should ideally achieve normal reference values and resemble the normal diurnal pattern. Evaluating serum testosterone levels both before and during treatment is imperative, although the efficacy of testosterone supplementation is best judged by clinical response rather than a precise testosterone determination. Current recommendations suggest that a short (e.g., 3-month) therapeutic trial is justified, and, in the absence of a response, testosterone administration should be discontinued (Wang et al, 2009; Bhasin et al, 2010). Potential adverse effects of androgen therapy (i.e., erythrocytosis, sleep apnea, urinary symptoms, prostate cancer progression risk, gynecomastia, acne) should be recognized (Morales et al, 2004; Wald et al, 2006). Monitoring of patients on therapy consists of a baseline assessment that includes digital rectal examination and serum PSA testing along with laboratory evaluation (i.e., hemoglobin/hematocrit levels, liver function tests, cholesterol level, and lipid

profile) followed by the assessment of treatment efficacy after 3 to 6 months and annually thereafter to ascertain symptom response and any adverse events (Morales et al, 2004; Bhasin et al, 2010). Short-acting preparations may be preferred in favor of long-acting depot preparations in the initial treatment of patients, so that therapy can be discontinued on the occasion of an adverse event (Wang et al, 2009).

For the treatment of hypogonadism, several testosterone preparations are offered and can be delivered by various routes: intramuscular, subcutaneous, transdermal (patch and gel), buccal, and oral (Edelstein et al, 2006; Morgentaler et al, 2008; Wang et al, 2009; Bhasin et al, 2010; Corona et al, 2011). A brief description of available therapies follows (see also Table 27-6).

Intramuscular. Testosterone enanthate or cypionate, an injectable depot preparation of testosterone, is delivered by deep intramuscular injection (200 to 250 mg every 2 to 3 weeks). The schedule of therapy results in supraphysiologic levels of testosterone for 72 hours with a steady exponential decline to subphysiologic levels by 10 to 12 days. Alternative dosing of 100 mg every 7 to 10 days can be considered in situations when patients experience symptomatic mood changes or sexual fluctuations associated with documented early hypogonadal troughs. Another parenteral preparation, testosterone propionate, is also delivered intramuscularly at a dosage of 200 mg every 2 to 3 days because of its shorter half-life, and it may also display serum testosterone fluctuations. Testosterone undecanoate (TU), as a depot formulation consisting of 750- or 1000-mg dosages administered at 10-week dosing intervals, has been used in Europe since 2003 although it is not yet available in the United States.

Subcutaneous. Pellets offer a subcutaneous, long-acting depot formulation of testosterone. Testopel is a pellet containing 75 mg of testosterone. Dosing usually requires 2 to 6 pellets (150 to 450 mg testosterone) implanted subcutaneously every 3 to 6 months.

Transdermal. Transdermal delivery options comprise patches and gels, with a delivery approach that intentionally simulates normal circadian levels of testosterone. When patients apply medication in the morning, higher initial absorption will mimic normal diurnal variation.

Testoderm was approved initially as a scrotal patch administered daily without adhesive (4 to 6 mg), but it came under disuse because of difficulties with its application, the requirement for scrotal shaving, and the finding that it significantly produced high levels of DHT by conversion by 5 α -reductase activity that is plentifully present in the scrotal skin. Testoderm TTS represented an alternative formulation avoiding the inconveniences of the scrotal application. Its application is to the arm, back, or buttock as a 5-mg patch. Androderm, an alternative product, delivers 2.5 or 5 mg of testosterone daily. Both patches have been associated with itching, chronic skin irritation, and allergic contact dermatitis. The skin irritation is alleviated by the local application of cortisone cream. Patients are advised to alternate application sites and avoid sun-exposed areas.

AndroGel (testosterone 1% gel) is a topical gel pack that contains 50, 75, or 100 mg of testosterone, with only 10% of the drug being absorbed during a 24-hour period. Testim, also providing 1% testosterone, is an alternative product packaged as a 5-g tube containing 50 mg of testosterone. Both are similarly applied once daily in the morning to clean, dry skin on the shoulders, upper arms, or abdomen, and it is allowed to dry before dressing. Axiron (testosterone 2% solution) is another transdermal product approved by the U.S. Food and Drug Administration (FDA), consisting of 30 mg of testosterone applied to each axilla once daily using a metered applicator. Special considerations for axillary administration include the concealable location and high permeability of the axilla, which has a relatively high level of 5- α reductase activity.

Buccal. Striant refers to a tabletlike, mucoadhesive treatment system (30 mg of testosterone) that continuously delivers medication. It is applied twice daily to the gum tissue above the incisors allowing testosterone to be absorbed through the buccal mucosa.

Oral. Oral testosterone preparations are limited. Concern is associated with the liver toxicity of testosterone (i.e., hepatitis, cholestatic jaundice, hepatomas, hemorrhagic liver cysts, and hepatocellular carcinoma) related to the large doses necessary to achieve normal serum levels (Bagatell and Bremner, 1996). Large doses (>200 mg/day) are required orally because much of the administration is rendered metabolically inactive during the “first-pass” circulation through the liver. Chemical modifications of oral testosterone have been explored to overcome adverse reactions. Both 17 α -methyltestosterone and fluoxymesterone have been formulated, but because of their patient variability of effect with potential liver toxicity risk they should not be prescribed (Wang et al, 2009). TU, as an oral formulation in oleic acid, is safe by partly escaping hepatic inactivation (Köhn and Schill, 2003). However, it has shown a large individual variability for the time of maximal responses as well as when maximal serum testosterone is attained. Oral TU remains unapproved in the United States.

Alternative Hormone Treatments

Alternative hormonal replacement therapies have been suggested, and they have posed certain desirable features as well as caveats. DHT as a direct mode of therapy is attractive because of its action as a pure androgen that is not aromatizable to estradiol, and accordingly it has been demonstrated that the hormone does not exert adverse estrogenic effects on prostate growth or lipid profile measurements (Kunelius et al, 2002; Sakhri and Gooren, 2007). A therapeutic DHT gel is available at a dose of 125 to 250 mg/day, yielding plasma DHT levels comparable to physiologic testosterone levels (Kunelius et al, 2002). Dehydroepiandrosterone (DHEA), a hormone supplement with androgen-like and estrogen-like effects, has been used, although limited evidence exists showing it improves sexual function (Baulieu et al, 2000; Morales et al, 2004). It is important to note that the treatment cannot be considered harmless, and the potential exists for DHEA and other nontestosterone androgen precursor preparations (e.g., DHEA-S, androstenediol, androstenedione) to stimulate hormone-sensitive diseases such as breast or prostate cancer. Human chorionic gonadotropin (HCG) has been found to increase total and free testosterone and estradiol 50% above baseline, and it would conceivably be of benefit to hypogonadal men in a way similar to the effects of androgen administration. Clinical investigation of HCG has shown some anthropometric effects (i.e., decrease in fat mass, increase in lean body mass) and improvements in serum testosterone concentrations in androgen-deficient men without documented benefits for sexual function (Liu et al, 2002; Tsujimura et al, 2005). Antiestrogens and aromatase inhibitors have been shown to increase endogenous testosterone levels, and selective androgen receptor modulators are under development. Because of insufficient evidence about the therapeutic benefits and adverse effects of alternative replacement therapies in older men with hypogonadism, they are not currently recommended for use (Wang et al, 2009).

Hyperprolactinemia Treatments

The treatment of hyperprolactinemia is undertaken with the acknowledgment that testosterone replacement therapy is neither corrective nor sufficient to improve sexual function. The therapeutic objective, rather, is to identify and address the underlying cause, which may then ameliorate ED. Offending drugs, such as estrogens, morphine, sedatives, and neuroleptics, should be discontinued (Molitch, 2008). A prolactin-secreting adenoma should be treated medically and if necessary surgically. Bromocriptine, a dopamine agonist that lowers prolactin level and restores testosterone to normal, serves to reduce the size of the tumor. Neurosurgical ablation becomes necessary if the therapeutic response to medication does not occur or visual effects are noted in association with optic-nerve compression (Gillam et al, 2006). Erection recovery is most evident after treatment of men with significant serum elevations of prolactin (higher than 40 ng/mL) (Netto Júnior and Claro, 1993).

TABLE 27-6 Testosterone Preparations

Formulation	Chemical Structure	T _½	Standard Dosage	Advantages	Disadvantages
Oral Agents					
Testosterone undecanoate	17- α -hydroxyl-ester	4 hr	120-240 mg 2-3 times daily	Oral convenience Modifiable dosage	Serum testosterone levels and clinical responses vary Must be taken with meals Potential hepatotoxicity Treatment considered obsolete Nonaromatizable to estrogen
Methyltestosterone	17- α -alkylated	3.5 hr	20-50 mg 2-3 times daily	Oral convenience Modifiable dosage	
Mesterolone	1-alkylated	8 hr	100-150 mg 2-3 times daily	Oral convenience Modifiable dosage	
Intramuscular Agents					
Testosterone enanthate	17- α -hydroxyl-ester	4-5 days	250 mg every 2-3 wk	Low cost Modifiable dosage	Wide fluctuations in circulating T levels Multiple injections Relative higher risk of polycythemia Wide fluctuations in circulating T levels Multiple injections Wide fluctuations in circulating T levels Multiple injections Relative higher risk of polycythemia Pain at injection site
Testosterone cypionate	17- α -hydroxyl-ester	8 days	200 mg every 2-3 wk	Low cost Modifiable dosage	
Testosterone propionate	17- α -hydroxyl-ester	20 hr	100 mg every 2 days	Low cost	
Testosterone undecanoate	17- α -hydroxyl-ester	34 days	1000 mg every 10-14 wk	Testosterone levels maintained within normal range Long lasting Less frequent administration	
Subcutaneous Agents					
Surgical implants	Native testosterone	—	4-6 200-mg implants lasting \leq 6 mo	Treatment only twice per yr	Placement is invasive Risk of extrusion and site infections
Controlled-release T-buccal Formulation Agents					
Testosterone buccal	Native testosterone	12 hr	30 mg 2 times daily	Testosterone levels within physiologic range	Possible oral irritation Twice-daily irritation Unpleasant taste
Transdermal Agents					
Testosterone patches	Native testosterone	10 hr	5-10 mg/day	Mimics circadian rhythm Simple administration	Skin irritation Daily administration
Testosterone gel 1%-2%	Native testosterone	6 hr	5-10 g/day	Testosterone levels maintained within normal range Flexible dose modification Skin irritation less common than with patches	Possible transfer during intimate contact Daily administration
Testosterone solution 2%	Native testosterone	NA	60-120 mg/day	Testosterone levels maintained within normal range	Possible transfer during intimate contact Daily administration

NA, not available; T, testosterone; T_{1/2}, drug half-time.

Modified from Corona G, Rastrelli G, Forti G, et al. Update in testosterone therapy for men. J Sex Med 2011;8:639-54.

Pharmacologic Therapies

The premise of pharmacologic therapies is that they simulate the biochemical and molecular mechanisms of action naturally governing the erectile response. Conceptually, erectogenic therapies serve strategically either to promote proerectile mechanisms or to oppose antierection mechanisms, at both peripheral and central levels of the neurovascular axis responsible for penile erection (Rowland and Burnett, 2000). At a peripheral level, these mechanisms influence corporeal smooth muscle tone. Promotion of proerectile mechanisms is achieved by either inducing corporeal smooth muscle activation through cell-receptor agonists or effectors of tissue relaxant pathways (e.g., stimulating second messenger cyclic nucleotide [cyclic guanosine monophosphate {cGMP} or cyclic adenosine monophosphate {cAMP}] synthesis) or inhibiting the deactivation of smooth muscle relaxation pathways (e.g., inhibiting phosphodiesterases), whereas opposition of antierection mechanisms are achieved by decreasing smooth muscle contraction through receptor antagonists of tissue contractile pathways (e.g., α_1 -adrenergic inhibitors). At a central nervous system level (i.e., brain or spinal cord), neuronal pathways are affected, and potential opportunities exist to promote proerectile pathways (e.g., agonists of dopaminergic D₂ receptors in the medial hypothalamus) or to oppose antierection pathways (e.g., antagonists of 5-HT_{1A/2} [serotonergic] receptors in the spinal cord).

Diverse therapies have been touted throughout time, although their efficacy and safety characteristics have not always been clearly defined. Current standards of regulatory agency approval have helped to clarify the qualifications of commercially developed and marketed therapies (Hirsch et al, 2004).

Oral Therapy

Orally administered medication for ED meets many of the attributes of “ideal therapy,” which include convenience, simplicity, and noninvasiveness (Morales et al, 1995). Oral therapies are increasingly in demand to meet the therapeutic objective of clinical efficacy as well.

Phosphodiesterase Type 5 Inhibitors. This class of medication was famously inaugurated as an effective ED treatment in the United States following the FDA approval of sildenafil citrate (Viagra, Pfizer, Inc., New York, NY) in 1998, vardenafil hydrochloride (Levitra, Bayer Schering Pharma AG, Berlin, Germany), and tadalafil (Cialis, Lilly LLC, Indianapolis, IN) in 2003, and avanafil (Stendra, Vivus Inc., Mountain View, CA) in 2012 (Bruziches et al, 2013; Porst et al, 2013). PDE5 inhibitors similarly work to block the catalytic action of the enzyme that degrades cGMP, the downstream effector of the erection mediator nitric oxide, which

then facilitates the signal transductional mechanisms of corpus cavernosal smooth muscle relaxation required for penile erection. It is important to recognize that the medications augment but do not induce the erectile response and the induction of penile erection requires the release of nitric oxide from penile nerve endings and vascular endothelium under the influence of sexual stimulation (Burnett, 2005). The high concentration of PDE5 inhibitors in the smooth muscle of the penile corpora cavernosa accounts for the selectivity of their effect.

Despite their similar modes of actions, PDE5 inhibitors differ somewhat in their biochemical properties, pharmacokinetic profiles, and clinical performances (Table 27-7). The chemical structure of PDE5 inhibitors are similar, containing a guaninelike base, a riboselike or desoxyribose-like system, and a phosphate diester-like bond, which confers their ability to bind effectively to the catalytic site of the PDE5 enzyme. The chemical structures of sildenafil and vardenafil are similar, unlike that for tadalafil, and this difference serves to explain some phenomenologic distinctions observed between these agents (Corbin and Francis, 1999). The chemical structure of avanafil differs from the standard model of the other three agents, which may account for some of its selective actions (Kedia et al, 2013). Distinct from the actions of tadalafil and avanafil, sildenafil and vardenafil cross-react to a greater extent with phosphodiesterase (PDE) type 6, which is expressed in the retina, and this difference may explain the complaint of visual disturbances observed with sildenafil and vardenafil use. Tadalafil minimally cross-reacts with PDE type 11, unlike the other three PDE5 inhibitors, although the significance of this effect is unclear. The remaining side effects commonly observed with PDE5 inhibitor treatment are associated with inhibition of PDE5 localized in other target tissues, such as vascular and gastrointestinal smooth muscle. Tadalafil possesses a longer half-life of elimination than the other three PDE5 inhibitors. This feature suggests a longer therapeutic window uniquely afforded for tadalafil, which may translate into increased convenience for couples having sexual intercourse with this agent.

All four PDE5 inhibitors have demonstrated equivalent efficacy and tolerability in clinical trials for the treatment of ED of varying severity and cause (Carson and Lue, 2005; Hellstrom, 2007; Giuliano et al, 2010; Bruziches et al, 2013; Porst et al, 2013; Yuan et al, 2013). Trial designs for these agents have differed, limiting useful comparisons among them, and superiority cannot be claimed for any particular agent in the absence of directly comparative studies (Carson and Lue, 2005; Khara and Goldstein, 2011). In general, the agents effectively result in successful sexual intercourse rates of approximately 70% (Carson and Lue, 2005; Khara and Goldstein, 2011). A somewhat reduced intercourse success rate of 40% to 50% has been reported in diabetic patients with ED (Fonseca et al, 2004;

TABLE 27-7 Comparison of Four Phosphodiesterase Type 5 Inhibitors Currently Available in the United States

	SILDENAFIL	VARDENAFIL	TADALAFIL	AVANAFIL
Cmax (ng/mL)	450	20.9	378	2153
Tmax (hr)	0.8	0.7-0.9	2	0.3-0.5
Onset of action (min)	15-60	15-60	15-120	15-60
Half-life (hr)	3-5	4-5	17.5	3-5
Bioavailability	40%	15%	Not tested	30%
Fatty food	Reduced absorption	Reduced absorption	No effect	Reduced absorption
Recommended dosage	25, 50, 100 mg	5, 10, 20 mg	5, 10, 20 mg	50, 100, 200 mg
Side effects:				
Headache, dyspepsia, facial flushing	Yes	Yes	Yes	Yes
Backache, myalgia	Rare	Rare	Yes	Rare
Blurred/blue vision	Yes	Rare	Rare	No
Precaution with antiarrhythmics	No	Yes	No	No
Contraindication with nitrates	Yes	Yes	Yes	Yes

Cmax, maximal plasma concentration; half-life, time required for elimination of one half of the medication from plasma; Tmax, time required to attain Cmax.

Safarinejad, 2004) and in patients with ED associated with radical prostatectomy in general (Hatzimouratidis et al, 2009). However, the intercourse success rate for patients after bilateral nerve-sparing radical prostatectomy specifically is somewhat better than for the entire group, and reports have commonly documented rates that approach 60% to 70% for functional erections with therapy.

According to standard dosing recommendations, patients are instructed to take the medications on demand between 30 and 60 minutes before intended sexual activity. This lead-time interval is specified to take advantage of the duration by which the medications achieve peak serum concentrations (i.e., approximately ½ hour for avanafil, 1 hour for sildenafil and vardenafil, and 2 hours for tadalafil). Although the onset of activity has been documented to occur possibly within 20 minutes for each agent, this characteristic is less important to patients than erection hardness and maintenance of erections with therapy (Claes et al, 2008). A daily dosing regimen has been approved for tadalafil as an alternative treatment schedule to afford patients greater convenience in having sexual intercourse while using this agent (Porst et al, 2006; Shabsigh et al, 2010). Optimization of effect for all PDE5 inhibitors is also achieved by applying sexual stimulation properly as a prerequisite for nitric oxide release, by reducing food intake, which may delay drug absorption, by escalating drug dosing as needed, and by repeating attempts with the medications several times (up to nine or ten attempts affords maximal probability of success) (McCullough et al, 2002; Barada, 2003; Shindel, 2009). Correcting or improving adverse health conditions (e.g., glycemic control, hyperlipidemic control, androgen replacement), which affect drug efficacy, has also been demonstrated as potentially beneficial (Guay, 2003; Sadowsky et al, 2009). As evidence of therapeutic efficacy, patient and partner satisfaction with therapy (as shown for sildenafil) has been well demonstrated (Montorsi and Althof, 2004). Suboptimal acceptance or lack of long-term adherence to therapy (up to 47% of patients) has been reported, which may indicate the influence of psychosocial factors or challenges of a treatment that requires repeated dosing (Seftel, 2002; Al-Shaiji and Brock, 2009).

BOX 27-1 Warnings and Drug Interactions

The package inserts of all four phosphodiesterase type 5 (PDE5) inhibitors warn against their use in patients with severe cardiovascular diseases and left ventricular outflow obstruction (e.g., aortic stenosis, idiopathic subaortic stenosis), those with severely impaired autonomic control of blood pressure, and patients not studied in clinical trials (U.S. prescribing information of Viagra, Cialis, and Levitra and Stendra, September 2013). These include patients with:

- Myocardial infarction, stroke, or life-threatening arrhythmia within the previous 6 mo
- New York Heart Association class II or greater heart failure or coronary artery disease causing unstable angina
- Resting hypotension (<90/50 mm Hg) or hypertension (>170/100 mm Hg)
- Known hereditary degenerative retinal disorders including retinitis pigmentosa
- Severe hepatic impairment (Child-Pugh C) or end-stage renal disease requiring dialysis

Certain drugs such as ketoconazole and itraconazole and protease inhibitors such as ritonavir can impair the metabolic breakdown of PDE5 inhibitors by blocking the CYP3A4 pathway. Such agents may increase blood levels of inhibitors, requiring a PDE5 dose reduction. On the other hand, agents such as rifampin may induce CYP3A4, enhancing the breakdown of inhibitors and requiring higher PDE5 doses. Kidney or hepatic dysfunction may require dose adjustments or warnings.

Patients using PDE5 inhibitors should be thoroughly counseled regarding precautions (Box 27-1). Cardiovascular safety using this class of compounds has been well demonstrated, although it should be emphasized that given the cardiovascular risks of sexual activity and potential for adverse drug interactions with this therapy, cardiovascular risk assessment and stabilization should be considered for all men before the institution of PDE5 inhibitor therapy. **Controlled and postmarketing studies involving these agents have shown that they do not cause an increase in myocardial infarction or death rates when compared with expected rates in study control populations** (Jackson et al, 2006a; Hellstrom, 2007; Nehra, 2009). In addition, patients with known coronary artery disease or heart failure receiving PDE5 inhibitors did not exhibit worsening ischemia, coronary vasoconstriction, or worsening hemodynamics on exercise testing or cardiac catheterization. Caution is advised for the use of PDE5 inhibitors in patients with certain conditions: aortic stenosis, left ventricular outflow obstruction, hypotension, and hypovolemia. The agents have a minimal effect on QTc interval (Morganroth et al, 2004). Vardenafil among PDE5 inhibitors is not recommended in patients who take type 1A antiarrhythmics (e.g., quinidine or procainamide) or type 3 antiarrhythmics (e.g., sotalol or amiodarone) or in patients with congenital prolonged QT syndrome.

Nitrate use in any form (e.g., sublingual nitroglycerin, isosorbide dinitrate, other nitrate preparations used to treat angina, amyl nitrite, and amyl nitrate “poppers”) represents an absolute contraindication. Past use of nitrates, that is, more than 2 weeks before the use of PDE5 inhibitors, is not considered a contraindication. If angina occurs during sexual activity when using a PDE5 inhibitor, patients should cease this activity and seek emergency care immediately. They should inform medical personnel that a PDE5 inhibitor was taken and should avoid nitroglycerin use for a period of 24 hours for sildenafil and vardenafil and 48 hours for tadalafil (Cheitlin et al, 1999). If acute myocardial infarction occurs with the use of PDE5 inhibitors, usual therapies, with the exception of organic nitrates, may be administered. If hypotension results from PDE5 inhibitor use, patients should be placed in the Trendelenburg position and given intravenous fluids along with administration of α -adrenergic agonists (e.g., phenylephrine) as needed. Refractory hypotension warrants intra-aortic balloon counterpulsation, as specified by the American College of Cardiology/American Heart Association guidelines. **No pharmacologic antidote to the PDE5 inhibitor/nitrate interaction exists.** Caution is advised when PDE5 inhibitors are coadministered with α -adrenergic blockers, because both agents are vasodilators with blood pressure lowering effects.

Side effects observed with PDE5 inhibitor therapy include headache (7% to 16%), dyspepsia (4% to 10%), flushing (4% to 10%), myalgia/back pain (0% to 3%), nasal congestion (3% to 4%), and visual disturbances (e.g., photophobia, blue vision) (0% to 3%). Randomized, controlled trials have documented that flushing and visual side effects are more common in patients receiving sildenafil or vardenafil, whereas back pain/myalgia is more common in patients receiving tadalafil. These events have been found to be mild and to abate with time, and the side effects prompt discontinuation only in few patients (Hellstrom, 2007; Porst et al, 2013). The concern has been posed with PDE5 inhibitor therapy regarding the development of nonarteritic anterior optic neuropathy (NAION), which can cause blindness, although several systematic reviews of the safety of this class of compounds have not shown an increased risk of NAION or other adverse ocular events associated with their use (Laties, 2009; Porst et al, 2013). Affected patients in postmarketing reports possibly carried risk factors for blindness to include hypertension, diabetes, and hyperlipidemia. At this time, despite the absence of a proven link between PDE5 inhibitor use and serious ocular disorders, physicians should continue to advise patients to stop use of PDE5 inhibitors and to seek immediate medical attention as a safety measure in the event of a sudden loss of vision (Laties, 2009; Porst et al, 2013).

The interest in extending the use of PDE5 inhibitors beyond an on-demand erectogenic role and rather applying them to

recovery or maintenance of the natural vitality of the penis in the face of an ED-associated disease state or condition has been investigated. This proposal has been considered particularly in the clinical context of radical prostatectomy and has been introduced as a therapeutic strategy à la “penile rehabilitation,” by which the medications are taken in some regularly scheduled fashion to promote the recovery of spontaneous erectile function. Presently, this role remains unclear, owing to limited well-designed and conducted (i.e., randomized, controlled) clinical trials of PDE5 inhibitor use in this clinical setting (Mulhall et al, 2013). In one supportive trial involving sildenafil treatment of 36 weeks starting 4 weeks after the surgery, 27% of patients using the agent recovered erections defined as “good enough for sexual activity” compared with 4% of patients on placebo at about 1 year after surgery (Padma-Nathan et al, 2008). However, in another trial involving vardenafil treatment of 9 months either on-demand or daily starting 14 days after surgery, erection recovery was no different in patients using vardenafil by either form of administration or placebo at about 1 year after surgery (Montorsi et al, 2008). Another trial randomizing patients to the use of sildenafil nightly or on-demand for 12 months with a 1-month washout showed that erection recovery was not different between patient groups (Pavlovich et al, 2013). Randomized, controlled trials in other ED contexts have also failed to show sustained natural erectile function improvement after discontinuing continuous regimens of PDE5 inhibitor therapy (Zumbé et al, 2008; Burnett et al, 2009).

The notion of combining PDE5 inhibitors with other ED therapies such as vasoactive penile pharmacotherapies has been proposed (Lau et al, 2006; McMahon et al, 2006). This strategy is to be considered “off-label,” and clinical precautions are advised.

α -Adrenoceptor Antagonists. Phentolamine mesylate is a non-specific α -adrenergic receptor antagonist with equal affinity for blocking both α_1 - and α_2 -adrenoreceptors. Its mode of action presumably is to produce corporeal smooth muscle relaxation by blocking the (antierectile) postsynaptic α_1 -adrenergic receptor (Juenemann et al, 1986). Clinical trials suggested an efficacy rate in men with minimal ED of approximately 40% (Goldstein, 2000). The drug was considered to be relatively safe, with less than 10% of patients using the 40-mg dosage experiencing headaches, facial flushing, or nasal congestion. However, further investigation is required before determining whether it will produce erectile responses of sufficient quality for reliable sexual intercourse, particularly in men with more severe ED.

Yohimbine hydrochloride (Yocon), an indolalkylamine alkaloid derived from the bark of the yohimbe tree, reportedly exerts central effects on the mediation of penile erection operating as an α_2 -adrenoreceptor antagonist (Clark, 1991; Giuliano and Rampin, 2000). Originally proposed to be an erectogenic and aphrodisiac agent, the drug has been investigated as an authentic ED treatment. It is conventionally prescribed orally at a dosage of 5.4 mg three times daily with observation for improvement throughout at least a month. A meta-analysis of all randomized, placebo-controlled trials involving yohimbine suggested a superior effect for the medication compared to placebo (Ernst and Pittler, 1998). However, the drug does not appear to enable successful sexual intercourse any better than placebo in men with confirmed organic ED (Montague et al, 1996; Telöken et al, 1998). Adverse effects appear to be relatively infrequent but include hypertension, anxiety, tachycardia, and headache. Although yohimbine may be well tolerated, its modest results suggest that it may be best limited to men with psychogenic ED (Porst et al, 2013).

Dopaminergic Agonists. Apomorphine (Uprima, TAP Pharmaceutical Products Inc., Lake Forest, IL) is a dopaminergic agent activating D_1 and D_2 receptors at a central level within the paraventricular nucleus of the brain, indicating its particular relevance in the treatment of men with psychogenic ED (Lal et al, 1987). The medication is administered in sublingual form with a dosage range of 2, 4, and 6 mg, and it has no erectile efficacy if it is swallowed (Heaton, 2000). It has a rapid onset of action, with a mean time to erection of 12 minutes. Apomorphine achieves a maximal plasma concentration in 50 minutes, although its window of opportunity

extends for approximately 2 hours from administration. In clinical trials involving men with ED of varying severities and etiologies, the drug achieved a successful sexual intercourse rate of 50.6% at the 4-mg dosage compared with the 33.8% placebo rate (Heaton, 2000). Side effects include nausea (16.9%), dizziness (8.3%), yawning (7.9%), somnolence (5.8%), sweating (5%), and emesis (3.7%). Syncope occurred in 0.6% of patients using the medication at the highest recommended dosage, and this was accompanied by a prodrome consisting of nausea, vomiting, sweating, dizziness, and light-headedness but no cardiac sequelae. Side effects were minimized when patients were titrated from higher to lower dosages. The drug achieved regulatory approval for commercialization by European authorities in early 2001, but it has not been so approved in the United States.

Melanocortin-Receptor Agonists. Melanocortin analogues (e.g., melanotan II, PT-141) have been studied showing efficacy in inducing erectile responses in early clinical trials (Wessells et al, 2000; Diamond et al, 2004). These drugs operate centrally at melanocortin-4 receptors, which have been implicated in controlling food intake and energy expenditure as well as modulating erectile function and sexual behavior. Flushing and nausea have been reported as side effects. The drugs have not achieved regulatory approval for the treatment of ED.

Serotonin-Receptor Effectors. Trazodone (Desyrel) is an antidepressant that has been associated with priapism, prompting its “off-label” investigation as a possible treatment for ED (Lal et al, 1990). It is purported to work through mechanisms at the spinal-cord level with multiple serotonergic effects (Allard and Giuliano, 2001). The active metabolite of trazodone acts as an agonist of the proerectile 5-HT_{2C} receptor through reuptake inhibition, with some affinity for the 5-HT_{2A} receptor, although it may also operate as an antagonist of antierectile 5-HT_{1A} receptors (Andersson and Wagner, 1995). Rigorous evaluations have not shown clinical efficacy that exceeds placebo responses in eliciting penile erection (Costabile and Spevak, 1999). Given its potential side effects (i.e., drowsiness, nausea, emesis, blood pressure changes, urinary retention, and priapism) and general lack of effect, this medication would appear to have a limited role for ED treatment.

Other Oral Therapies. Additional possibilities for the oral treatment of ED, including L-arginine (the amino acid precursor of nitric oxide), L-dopa (dopamine precursor), limaprost (prostaglandin E₁), and naltrexone (opioid antagonist), have been proposed (Burnett, 1999). Each of these agents has a plausible mechanism of action to induce erections. However, they remain insufficiently studied, and their clinical roles remain unclear (Porst et al, 2013).

Intracavernosal Injection

The discovery in 1982 that vasoactive agents, delivered by injection into the penis, induced erections is credited with launching the movement toward medical therapies for the treatment of ED (Virag, 1982; Zorngiotti, 1985). Since that time, there has been an explosion of basic scientific and clinical research leading to the development and use of various locally administered vasoactive medications having mechanisms of action that result in corporeal smooth muscle relaxation. Although a host of medications have been explored for this purpose, three medications are used regularly in clinical practice: alprostadil, papaverine, and phentolamine (Table 27-8). These have been administered clinically as a single agent (i.e., monotherapy) or in various combinations (e.g., bimix, trimix). Combination therapy offers a synergistic mechanism of the vasoactive agents to elicit maximal erectile responses, particularly among patients who have failed monotherapy (Zorngiotti and Lefleur, 1985; Bennett et al, 1991; Floth and Schramek, 1991; Khera and Goldstein, 2011; Porst et al, 2013). This alternative may also be used to circumvent side effects of a certain agent (e.g., penile pain associated with alprostadil).

A general rule of thumb is to start with a small dose of medication, especially in patients with nonvasculogenic forms of ED. In-office self-injection training and education are recommended before home injection, and this opportunity may also be used to

TABLE 27-8 Intracavernosal Pharmacotherapies

TRADE NAME	DRUG	DOSAGES	EFFICACY (INTERCOURSE)
Caverject	Alprostadil (Prostin VR)	5–40 µg/mL	≈70%
Viradal/Edex	Alprostadil (Prostin VR)	5–40 µg/mL	≈70%
Bimix	Alprostadil + phentolamine	20 µg/mL + 0.5 mg/mL	≈90%
Bimix Androskat (EU)	Papaverine + phentolamine	30 mg/mL + 0.5 mg/mL	≈90%
Trimix	Alprostadil + papaverine + phentolamine	10 µg/mL + 30 mg/mL + 1.0 mg/mL	≈90%
Invicorp	VIP + phentolamine	NA	≈80%

EU, European Union; NA, not available; VIP, vasoactive intestinal polypeptide.

titrate medication toward a dosage that safely yields an erection of sufficient rigidity for sexual intercourse yet lasts no more than an hour (Bénard and Lue, 1990; Fallon, 1995). The therapy is contraindicated for men with psychological instability, a history or risk for priapism, histories of severe coagulopathy or unstable cardiovascular disease, reduced manual dexterity (although the partner can be trained in the injection technique), and use of monoamine oxidase inhibitors (because of the risk of precipitating a life-threatening hypertensive crisis in the event that an intracavernosal α -adrenergic agonist is used to reverse a priapic episode) (Sharlip, 1998).

Alprostadil. Alprostadil (Prostin VR) is a synthetic form of a naturally occurring fatty acid, prostaglandin E_1 , which binds with specific receptors on smooth muscle cells and activates intracellular adenylate cyclase to produce cAMP, which in turn induces tissue relaxation through a second messenger system (Palmer et al, 1994). It currently is the only FDA-approved injectable medication for ED, and it is marketed for this purpose under the trade names Caverject (Pfizer Inc., New York, NY) and Viradel/Edex (Schwarz Pharma, Milwaukee, WI) (Linnet and Ogrinc, 1996; Porst, 1996; Buvat et al, 1998). After intracavernosal injection, the medication is locally metabolized by 96% within 60 minutes and does not appreciably enter the peripheral circulation (van Ahlen et al, 1994). At dosages of 10 to 20 µg, alprostadil produces full erections in 70% to 80% of patients with ED (Linnet and Neff, 1994; Khera and Goldstein, 2011; Porst et al, 2013). The most common side effects of treatment are pain at the injection site or during erection (in 11% of patients), hematoma/ecchymosis (1.5%), prolonged erection/priapism (1% to 5%), and penile fibrotic lesions (2%) (Linnet and Ogrinc, 1996). Perceived advantages of alprostadil for intracavernosal pharmacotherapy relative to other agents are lower incidences of prolonged erection, systemic side effects, and penile fibrosis. Disadvantages include a higher incidence of painful erection and higher cost, and, after reconstitution into liquid from powder, alprostadil has a shortened half-life if not refrigerated.

Papaverine. Papaverine, an alkaloid isolated from the opium poppy, is a nonspecific PDE inhibitor that prevents the degradation of cAMP and cGMP so that these cyclic nucleotides accumulate in smooth muscle cells and thereby increasingly promote tissue relaxation (Kukovetz et al, 1975). The compound also blocks voltage-dependent calcium channels along the membrane wall, thus impeding calcium influx to the cell, a process known to trigger smooth muscle contraction (Brading et al, 1983; Sunagane et al, 1985). Papaverine is metabolized in the liver, and the plasma half-life is 1 to 2 hours. Its general efficacy in promoting penile erection after intracavernosal administration is approximately 60% (Porst et al, 2013). The drug is inexpensive and stable at room temperature. However, disadvantages include commonly observed liver enzyme elevations, priapism risk (up to 35%), and penile fibrosis risk (1% to 33%), which have led to its abandonment as monotherapy (Lakin et al, 1990; Fallon, 1995; Porst, 1996; Moemen et al, 2004).

Phentolamine. In addition to its purported oral role for ED therapy, phentolamine mesylate is more familiarly applied as an intracavernosal agent (Regitine). Although its erectogenic effect is mediated by blocking the (antierectile) postsynaptic α_1 -adrenergic

receptor (Sironi et al, 2000), because of its potential inhibition of the prejunctional α_2 -adrenergic receptor, which interferes with norepinephrine reuptake, the drug's tissue relaxant effect for penile erection is believed to be antagonized (Juenemann et al, 1986). This dual effect of the drug probably accounts for its limited success when administered intracavernosally as a sole agent (Blum et al, 1985). It has a short plasma half-life (30 minutes). Common side effects associated with the drug include systemic hypotension, reflex tachycardia, nasal congestion, and gastrointestinal upset.

Vasoactive Intestinal Polypeptide. Vasoactive intestinal polypeptide (VIP), a hormone having 28 amino acids originally isolated from the small intestine, was proposed early on to be the elusive nonadrenergic noncholinergic (NANC) mediator of penile erection because of its potent vasodilatory effects in various tissues (Adaikan et al, 1986). Its mechanism of action in smooth muscle is achieved through specific protein receptor binding and activation of adenylate cyclase, thereby promoting synthesis of cAMP and subsequent tissue relaxation (Anderson and Wagner, 1995). The drug has had disappointing effects when administered alone, although when separately combined with other drugs such as papaverine and phentolamine, erection responses were elicited (Kiely et al, 1989; Dinsmore and Wyllie, 2008). VIP in combination with phentolamine (Invicorp) is currently being sought for regulatory approval in the United States.

Intraurethral Suppositories

The administration of vasoactive drugs via the urethral channel of the penis was introduced with the hope of affording a less invasive procedure than intracavernosal needle injections to induce penile erection. This technique relies on the absorption of the medication through the mucosal lining into the surrounding corpus spongiosum, with passage via small vascular channels into the main erectile bodies, the corpora cavernosa. The transfer of drug from the urethra to the cavernous tissue varies across men according to anatomic variability. Following an initial trial, which demonstrated that prostaglandin E_2 was effective in inducing full tumescence in 30% of patients and partial tumescence in 40% of patients (Wolfson et al, 1993), a synthetic formulation of prostaglandin E_1 was developed and the FDA approved it in November 1996 as MUSE (Medicated Urethral System for Erection, MEDA Pharmaceuticals, Inc., Somerset, NJ) (Hellstrom et al, 1996; Padma-Nathan et al, 1997). MUSE uses a suppository inserted into the urethral opening that dispenses a semisolid pellet (1 × 3 mm) of alprostadil (125, 250, 500, and 1000 µg dosages) into the distal urethra (3 cm from the external urethral meatus). Several technical procedures optimize the success of the treatment including properly depositing and manually distributing the medication into the penis and the patient's remaining in the upright position for several minutes after its application. In-office training and monitoring of initial response may afford advantages for optimizing technique and making dosage adjustments before performing the treatment at home.

A calculated final responder rate to MUSE is approximately 50%, and among responders approximately 70% of administrations result in sexual intercourse (Hellstrom et al, 1996;

Padma-Nathan et al, 1997; Guay et al, 2000; Khera and Goldstein, 2011; Porst et al, 2013). The combined use of an adjustable penile constriction band (ACTIS) was designed and was approved by the FDA to enhance the local retention and effect of the medication (Lewis, 2000). A transurethral bimix consisting of alprostadil and α_1 -adrenergic antagonist prazosin (ALIBRA) was introduced and in a multicenter trial of nearly 400 patients was shown to increase the at-home responder rate for successful sexual intercourse from 47% with alprostadil alone to 70% with ALIBRA (Qureshi, 2001).

Intraurethral therapy is perceived to have a niche role, associated with its inferior efficacy both with regard to PDE5 inhibitors and intracavernosal self-injection therapy (Khera and Goldstein, 2011; Porst et al, 2013). The main indications for this therapy are patients who are nonresponsive to PDE5 inhibitors resulting from damage of the autonomic penile nerve supply (e.g., radical prostatectomy, cystectomy, and trauma) or those who wish to use the therapy in combination with PDE5 inhibitors. Another rare indication for intraurethral therapy is patients complaining about a soft (cold) glans syndrome, which may occur after penile prosthesis implantation or as a clinical entity itself (Porst et al, 2013).

The most common side effects of MUSE include local urogenital pain (approximately one third of patients) and minor urethral bleeding (5%) (Padma-Nathan et al, 1997; Guay et al, 2000). Other complications such as hypotension (3%), dizziness (4%), and priapism (0.1%) have been observed as well. MUSE is contraindicated in patients with known hypersensitivity to alprostadil, abnormal penile anatomy, and conditions that increase the risk of priapism. MUSE seems safe for female partners, producing only a 5.8% incidence of vaginal burning or itching, although it should not be used without a condom for intercourse with a pregnant woman.

Transdermal/Topical Pharmacotherapy

The notion to apply vasoactive drugs directly to the surface of the penis is consistent with the general appeal of many transdermal therapies (e.g., gels and creams) in medicine based on their delivery route: convenience, simplicity, and putatively limited systemic adverse effects. Several topical therapies have been explored for ED treatments, although certain obstacles have limited their widespread use. Nitroglycerin, a nitric oxide donor formulated as a 2% paste, was found to produce tumescence but rarely penile rigidity sufficient for sexual intercourse (Owen et al, 1989). This relative inefficacy combined with its headache side effects for both patient and partner following absorption and action of the drug as a potent systemic vasodilator have precluded its use in clinical practice. Papaverine, formulated as a gel, was investigated but then abandoned as a topical ED treatment when it was found that its large molecular size (molecular weight 376 Da) interfered with its transdermal absorption (Kim et al, 1995).

Alprostadil has been a more promising prospect, subjected to commercial development for penile glans administration in combination with transdermal delivery enhancers: alprostadil 0.3% in combination with a proprietary permeation enhancer, referred to as Vitaros (Apricus Biosciences, San Diego, CA), and alprostadil combined with NexACT, referred to as Alprox-TD (NexMed, Inc., Robbinsville, NJ). Applied intrameatally, such agents in clinical trials have shown efficacy with rates of vaginal penetration and intercourse success that were small but significantly greater than placebo rates and caused minor side effects of site-specific burning or warmth that were comparable to placebo rates (McVary et al, 1999; Goldstein et al, 2001; McMahon, 2002; Padma-Nathan and Yeager, 2006; Rooney et al, 2009; Porst et al, 2013). Prostaglandin E_1 ethyl ester, which is a prodrug of prostaglandin E_1 , is believed to possess an improved transdermal permeation and less skin irritation than enhancing agents because of its esterification (Schanz et al, 2009). Applied to the shaft of the penis in early clinical trials, this drug achieved significantly higher rigidity scores than placebo. In general, transdermal therapy with alprostadil is likely to meet similar clinical roles as that assigned to transurethral pharmacotherapy. Further clinical trials will be useful to define and establish their place in the treatment of ED.

Medical Device

In patients who do not respond to or who decline oral or local vasoactive pharmacotherapeutic options, vacuum erection device therapy may be alternatively explored. The principle of vacuum erection device therapy is to mechanically create negative pressure surrounding the penis to engorge it with blood and then restrain blood egress from the organ to maintain the erection-like effect (Nadig et al, 1986; Broderick et al, 1992). Although the treatment does not produce a truly physiologic erection and the engorged blood predominantly consists of venous blood (Bosshardt et al, 1995), the effect resembles a normal erection and is sufficient for coitus. A particular feature is that the glans penis, and not solely the corpora cavernosa, is engorged with blood by the treatment, such that the treatment is further advantageous for patients experiencing glanular insufficiency (soft glans syndrome).

The standard vacuum erection device consists of a usually clear plastic suction cylinder and vacuum-generating source (manual or battery-operated pump) in one piece. It is placed directly over the flaccid penis and operated, and after the penis is erected an elastic constriction ring or band is positioned at the base of the penis; then the vacuum is released and the device is removed (Montague et al, 1996; McMahon, 1997). The cylinder has a pressure-release valve designed to prevent penile injury from excessive negative pressure. Sexual intercourse may then ensue, although it is recommended that the ring should not be left in place for longer than 30 minutes. Prescription devices are advised, and metal or other inelastic rings are contraindicated.

Efficacy rates as high as 90% have been reported for achieving satisfactory erections for ED associated with various severities and etiologies, but satisfaction rates with the device are lower, ranging commonly from 30% to 70% (Hellstrom et al, 2010; Porst et al, 2013). Attrition is reported to occur and may relate to lack of efficacy with more severe forms of ED, although long-term continuation rates have ranged up to 60% (Porst et al, 2013). Success is limited in patients with severe vascular abnormalities such as proximal venous leakage or arterial insufficiency or fibrosis secondary to priapism or prosthesis infection (Marmar et al, 1988). Patient preferences also dictate long-term success. The device is more acceptable to older men in a steady relationship compared to young, single men. Among basic expectations of the treatment, patients should be informed of possible local discomfort or pain associated with the constriction band, a pivoting effect of the penis because turgidity exists only distal to the band's location, a cyanotic discoloration and coolness of the penis resulting from extracorporeal congestion, and trapping of the ejaculation caused by urethral constriction (Witherington, 1989; Sidi et al, 1990; Cookson and Nadig, 1993). Common complications are minor and include penile pain and numbness, difficult ejaculation, ecchymosis, and petechiae, and major complications (e.g., penile skin necrosis, urethral varicosities, Fournier gangrene) are infrequent. Patients receiving anticoagulant therapy (e.g., aspirin, warfarin) and patients with bleeding disorders should use the device with caution (Limoge et al, 1996). Special uses for this therapy have been sought. It has been successfully combined with oral, intracavernosal, and intraurethral pharmacotherapies to produce erectile responses (Marmar et al, 1988; Chen et al, 1995; John et al, 1996; Chen et al, 2004; Canguven et al, 2009). The device has enhanced erectile effects in the presence of a malfunctioning penile prosthesis (Sidi et al, 1990; Korenman and Viosca, 1992). Further, it may offer a means to preserve the elasticity of penile tissues after priapism or penile prosthesis explantation (Moul and McLeod, 1989; Soderdahl et al, 1997) or after surgical correction of Peyronie disease (Yurkanin et al, 2001), and it has been suggested to facilitate erection recovery after treatments for prostate cancer (Raina et al, 2006; Köhler et al, 2007).

Surgery

Surgical interventions have always served an important role in the armamentarium of ED treatments. They are often applied in the

face of penile injury resulting from genital or pelvic trauma, penile structural deformity occurring in association with Peyronie disease, or possibly cavernosal fibrosis secondary to prolonged ischemic priapism or infection. They are also considered when medical therapy for ED is contraindicated, unsuccessful, or undesirable.

Penile Prosthesis Surgery

Penile prosthesis or implant surgery is a mechanism for creating penile rigidity that differs from a physiologic or pharmacologically induced erection. Malleable (semirigid) and inflatable (hydraulic) devices are both currently available for this purpose. Details of this treatment option are presented elsewhere.

Penile Revascularization Surgery

Based on the requirements of inflow of blood and its retention in the penis for penile erection to occur, it is hardly a wonder to think that vascular surgeries have aggressively been pursued to facilitate or restore these biologic processes.

Arterial Revascularization. In concept, arterial revascularization surgery was designed to create arterial inflow to the corpora cavernosa, in turn addressing the presentation of arteriogenic ED. Several procedures have been described to meet this objective, similarly creating an anastomosis of the inferior epigastric artery either to the corpus cavernosum directly or to vascular conduits of the penis such as the dorsal artery (i.e., revascularization), the deep dorsal vein (i.e., arterialization), or the deep dorsal vein with venous ligation (i.e., arterialization with venous reconstruction) (Hellstrom et al, 2010). Success of these surgeries has been variable and depends on careful patient selection. Penile arteriography is required to establish a penile arterial anatomic defect, and other organic causes of ED (e.g., venous incompetence) that would limit surgical success should be excluded. According to the current literature, the following inclusion criteria should be met when selecting patients for arterial surgery: age less than 55 years, nonsmoker, nondiabetic, absence of venous leakage, and radiographic confirmation of stenosis of the internal pudendal artery (Hellstrom et al, 2010; Sohn et al, 2013). The highest success rates are reported in young men (less than 30 years of age) with isolated arterial stenosis following perineal or pelvic trauma (Babaei et al, 2009). Complications of arterial revascularization surgery include glans hyperemia (13%), shunt thrombosis (8%), and inguinal hernias (6.5%) (Manning et al, 1998; Kawanishi et al, 2004).

Venous Reconstruction. Venous reconstruction was proposed to prevent the pathologic blood egress from the penis, understandably serving to correct veno-occlusive ED. Most surgical procedures have centered on ligating or embolizing penile veins (e.g., superficial dorsal vein, deep dorsal vein, crural vein) or surgically compressing the penile crura (e.g., crural plication/ligation, pericavernoplasty) (Hellstrom et al, 2010). Success with these surgeries has not been affirmed, owing primarily to inaccurate or deficient methods for diagnosing and correcting the relevant anatomic defect. The optimal surgical approach remains to be defined, and thus venous reconstructive surgery is presently considered investigational (Montague et al, 2005; Hellstrom et al, 2010; Sohn et al, 2013). Reported complications of this surgery include glanular hypo/anesthesia, skin necrosis, wound infections, penile curvature/shortening, and glans hyperemia.

Combination Therapies

It is well recognized that many patients with ED will not respond acceptably to monotherapy, with nonresponder rates documented as high as 40% of patients (Porst et al, 2013). Some patients indeed may achieve optimal therapeutic responses by combining treatment options. In addition, it is possible that a dose-limiting adverse effect is associated with ED monotherapy such that combined treatments may then seem advantageous. Multiple combinations may

certainly be proposed for ED treatment. The extant literature describes several successful combinations: oral PDE5 inhibitors with psychosocial counseling (Althof et al, 2005), oral PDE5 inhibitors with testosterone replacement therapy (Shabsigh et al, 2004), oral PDE5 inhibitors with transurethral alprostadil (Mydlo et al, 2000; Nehra et al, 2002), oral PDE5 inhibitor and intracavernosal pharmacotherapy (McMahon et al, 1999), oral PDE5 inhibitor and vacuum erection device (Chen et al, 2004; Canguven et al, 2009), intracavernosal pharmacotherapy and vacuum erection device (Chen et al, 1995), transurethral pharmacotherapy and vacuum erection device (John et al, 1996), and transurethral pharmacotherapy and penile prosthesis surgery (Benevides and Carson, 2000). Caution is advised when initiating combination therapy to observe for potential complications that may be compounded by combined treatments, and in-office evaluations before continuing treatments at home may be considered to offer an additional measure of safety.

Alternative Therapies

Alternative therapies have long been considered for the treatment of ED, from herbs, ointments, and concoctions of antiquity to vitamins, nutraceuticals, and dietary supplements in commercial supply today. The movement toward alternative medicines in this field actually gained momentum during the past decade with the emergence of effective oral therapy in the form of PDE5 inhibitors, which created avenues for producing PDE5 inhibitor-like counterfeit and imitation substances and promoting regulatory agency unapproved products in general. Indeed, the true efficacies of proposed alternative therapies (e.g., ginkgo biloba, L-arginine, Korean red ginseng) remain uncertain in the absence of evidenced benefit in rigorously performed, randomized, controlled clinical trials (Moyad et al, 2004; Khera and Goldstein, 2011). The success of these products is ascribed in some measure to the known placebo effect of agents to treat ED, which has been observed to amount to as much as 25% to 50% in properly conducted clinical trials. Before the use of alternative therapies can be advocated, further research that demonstrates their mechanisms of action and meaningful efficacies must be performed.

KEY POINTS: TREATMENT CONSIDERATIONS

- An informed decision-making process that combines goals and preferences of the patient (and partner) and balanced and thorough guidance of the clinician should dictate the best therapeutic option.
- Although definitive evidence is necessary to affirm the benefits of risk modification for preserving erectile health, recommendations are offered to maintain a healthy and fit lifestyle for this purpose.
- Patient education and counseling and application of medical therapies as initial forms of ED management constitute basic management in common practice.
- Psychosexual therapy offers a role in the integrative management of ED.
- Several pharmacotherapies administered by various modalities including oral, intracavernosal, intraurethral, and transdermal/topical routes are successfully applied or are under study as ED treatments.
- Vacuum erection device therapy offers an alternative to oral or local vasoactive pharmacotherapeutic options for ED.
- Surgical intervention, principally penile prosthesis surgery, represents an important ED treatment and may be considered when medical (nonsurgical) therapy is contraindicated, unsuccessful, or undesirable.
- Arterial revascularization surgery is offered only to selected patients with ED who meet stringent clinical and radiographic criteria for surgical success.

FUTURE DIRECTIONS

Impressive progress has been made in the field of ED management, encompassing all areas of epidemiology, basic scientific research, clinical investigation, and health services research. Future directions will assuredly continue with particular interest directed to new therapeutics. In the near future, pharmacotherapies will likely remain center stage, further driven by research discoveries in the molecular and cellular mechanisms responsible for the erectile response. Technologic advances in the way of interventional devices have rapidly gained interest. Alternatives such as implanting zotarolimus-eluting peripheral stents in atherosclerotic lesions of the internal pudendal arteries (Rogers et al, 2012) and low-intensity extracorporeal shockwave therapy applied to the penis (Vardi et al, 2012) are currently under study, supporting the idea that these and other such interventions may achieve the goal of restoring erectile function or improving it effectively for the long term. Futuristic approaches such as gene therapy, stem-cell therapy, and tissue engineering have been mainly advanced at the preclinical stage of development with the same long-term purpose, although their eventual roles remain eagerly anticipated. The future of this field looks excit-

ing and should foster the very best outcomes for patients experiencing ED.

Medical Treatments

Surgical Management of Ischemic Priapism

Interventional Angiography in the Management of Arterial (Nonischemic, High-Flow) Priapism

Surgical Management of Arterial (Nonischemic, High-Flow) Priapism

Summary

Priapism is a persistent erection arising from dysfunction of the mechanisms regulating penile tumescence, rigidity, and flaccidity. A correct diagnosis of priapism is a matter of urgency requiring identification of the underlying hemodynamics.

Scientific organizations have recommended guidelines for the management of priapism, including the American Urological Association (AUA) in 2003 (www.auanet.org) and the International Society for Sexual Medicine in 2006 (www.issm.info). Both groups have noted that the literature on priapism is composed mainly of small case series and individual case reports and includes inconsistent definitions and methodologies with few long-term erectile function outcome data. Recent case series have included detailed methodology including duration of priapism, cause of priapism, and erectile function outcomes. The basic science on the pathogenesis of priapism and clinical research supporting the most effective treatment strategies are summarized in this chapter. Recommendations for best clinical practice and suggestions for research are made.

DEFINING PRIAPISM

Priapism is a full or partial erection that continues more than 4 hours beyond sexual stimulation and orgasm or is unrelated to sexual stimulation.

Ischemic Priapism (Veno-Occlusive, Low-Flow)

Ischemic priapism is a persistent erection marked by rigidity of the corpora cavernosa (CC) and little or no cavernous arterial inflow. In ischemic priapism there are time-dependent changes in the corporal metabolic environment with progressive hypoxia, hypercarbia, and acidosis. The patient typically reports penile pain after 6 to 8 hours, and the examination reveals a rigid erection. The condition is analogous to a muscle compartment syndrome, with initial occlusion of venous outflow and subsequent cessation of arterial inflows. Well-documented histologic changes occur within the corporal smooth muscle as a consequence of prolonged ischemia. Interventions beyond 48 to 72 hours of onset may help relieve erection and pain but have little benefit in preserving potency. Histologically, by 12 hours corporal specimens show interstitial edema, progressing to destruction of sinusoidal endothelium, exposure of the basement membrane, and thrombocyte adherence at 24 hours. After 48 hours thrombus can be found in the sinusoidal spaces, and smooth muscle necrosis

with fibroblast-like cell transformation is evident (Spycher and Hauri, 1986). Ischemic priapism is an emergency. When left untreated, resolution may take days and erectile dysfunction (ED) invariably results (Fig. 28-1A and B).

Stuttering Priapism (Intermittent)

Stuttering priapism is characterized by a pattern of recurrence. The term has historically described recurrent unwanted and painful erections in men with sickle cell disease (SCD) (Serjeant et al, 1985). Patients typically awaken with an erection that persists for several hours. Males with SCD may experience stuttering priapism from childhood; in these patients the pattern of stuttering may increase in frequency and duration, leading to a full episode of unrelenting ischemic priapism. Any patient who has experienced an episode of ischemic priapism is also at risk for stuttering priapism.

Nonischemic Priapism (Arterial, High-Flow)

Nonischemic priapism is a persistent erection caused by unregulated cavernous arterial inflow. Typically, the corpora are tumescent but not rigid and the penis is not painful. A history of blunt trauma to the penis or an iatrogenic needle injury is common. Whatever the mechanism of injury, the result is a disruption of the cavernous arterial anatomy creating an arteriolar-sinusoidal fistula. The cavernous environment does not become ischemic and cavernous blood gases do not show hypoxia, hypercarbia, or acidosis. This type of priapism, once properly diagnosed, does not require emergent intervention. Beyond the acute trauma, patients do not report pain. Normal erectile function has been reported after recovery from the initial event, despite persistence of nonsexual partial erection.

PRIAPISM: HISTORICAL PERSPECTIVES

The term *priapism* has its origin in reference to the Greek god Priapus, who was worshipped as a god of fertility and protector of horticulture. Priapus is memorialized in sculptures for his giant phallus. The first recorded account of priapism in English medical literature appears in the *Lancet* and is attributed to Tripe (1845). Historically, the most commonly cited observation on this condition in North American literature is Frank Hinman Sr's

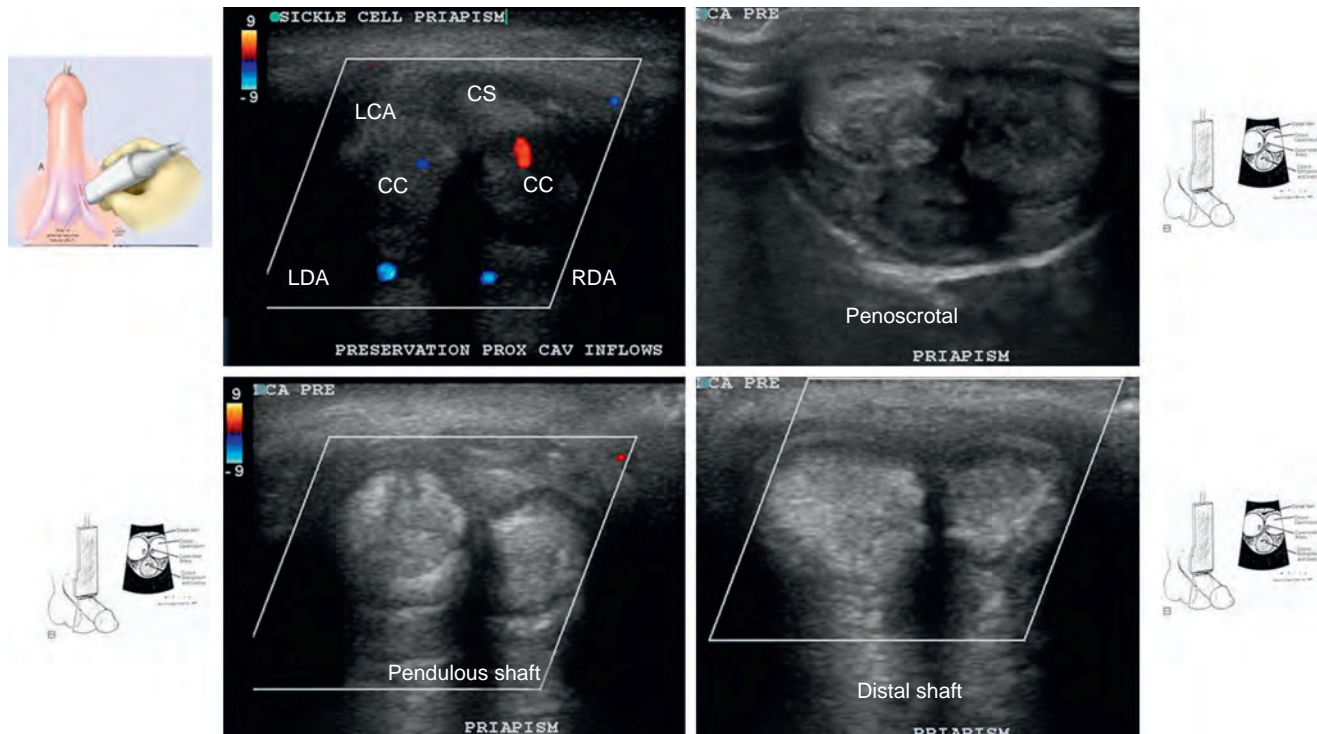

Figure 28-1. This 21-year-old Nigerian man had erectile dysfunction after recurrent episodes of sickle cell ischemic priapism. A, Transperineal imaging with color Doppler shows preservation of cavernous arterial inflow at the origin in the corpora cavernosa. B to D, Increasing echogenicity on gray-scale ultrasound of the penile shaft: penoscrotal, pendulous shaft, and distal shaft. These findings are the result of recurring ischemic priapism, which leaves the patient with distal corporal fibrosis. CC, corpora cavernosa; CS, corpus spongiosum; LCA, left cavernous artery; LDA, left dorsal artery; RDA, right dorsal artery.

landmark article describing the natural history of priapism (Hinman, 1914). Subsequently in 1960 his son, Frank Hinman Jr., proposed that venous stasis, increased blood viscosity, and ischemia were responsible for priapism and emphasized that failure to correct these abnormalities in the penile environment was essentially responsible for treatment nonresponse (Hinman, 1960). Advances in our understanding of the physiology of erection and the pathophysiology of ED substantiated early hypotheses that prolonged veno-occlusion within the corporal bodies is analogous to a compartment syndrome. Hauri and colleagues demonstrated the radiologic differences between veno-occlusive and arterial priapism (1983).

Frank Hinman (1914) first described “acute transitory attacks of priapism” as opposed to persistence or rapid recurrence of a single episode. The actual term *stuttering priapism* is attributed to Emond and colleagues (1980) in observations of patients with SCD in a Jamaican clinic. Stuttering priapism episodes were seen to increase in frequency and length, leading to major, unrelenting occurrence of ischemic priapism. Attempts to manage SCD patients with stuttering ischemic priapism resulted in the early recommendation for hormonal suppression of nocturnal erections and stuttering with estrogen (Serjeant et al, 1985).

Nonischemic priapism is described far less commonly than ischemic priapism in the urologic literature. Nonischemic priapism is invariably associated with antecedent perineal or penile trauma. It was first described in the English literature by Burt (Burt et al, 1960).

EPIDEMIOLOGY AND PATHOPHYSIOLOGY OF PRIAPISM

Etiology of Ischemic Priapism (Veno-Occlusive, Low-Flow)

Ischemic priapism accounts for the majority of cases described in the literature. The erection of ischemic priapism may begin with

KEY POINTS: PRIAPISM DEFINITIONS

- Priapism is a full or partial erection that continues more than 4 hours beyond sexual stimulation and orgasm or is unrelated to sexual stimulation.
- Ischemic (low-flow) priapism is a persistent erection marked by rigidity of the CC, with little or no cavernous arterial inflow.
- Nonischemic (arterial, high-flow) priapism is a persistent erection caused by unregulated cavernous arterial inflow. The corpora are tumescent but not rigid, and the erection is not painful.
- Stuttering priapism describes a pattern of recurrence. The term has traditionally described recurrent prolonged and painful erections in men with SCD.

sexual stimulation or the administration of pharmacologic agents. Once an erection persists beyond 4 hours and is not relieved by orgasm or pharmacologic reversal, the pathophysiologic phenomena of ischemic priapism have begun. Erections lasting up to 4 hours are by consensus defined as “prolonged”; manufacturers of erection-facilitating pharmacotherapies (oral, injectable, and intraurethral) recommend that the patient seek emergent medical consultation for prolonged erection.

Population-based studies estimate cases per 100,000 person-years (the number of patients with a first episode of priapism divided by the accumulated amount of person-time in the study population). Cases per 100,000 person-years have been calculated in several countries; these data depend on recording of presentations to clinics and hospitals where cases are registered. Kulmala and colleagues (1995) calculated the cases per 100,000 person-years

to be 0.34 to 0.52 from 1975 to 1990 in Finland; [Eland and colleagues \(2001\)](#) calculated the cases in the Netherlands to be 1.5 per 100,000 person-years; [Earle and colleagues \(2003\)](#) calculated 0.84 per 100,000 person-years in Australia from 1985 to 2000. These reported incidence rates were statistically significantly affected by the introduction and proliferation of intracavernous vasoactive injections for the management of ED; in Finland during the last 3 years of the study the incidence of priapism doubled to 1.1 cases per 100,000 person-years. These and other reports on the epidemiology and etiology of priapism are also greatly influenced by the prevalence of SCD in the populations described. **The lifetime probability of a man with SCD developing ischemic priapism ranges from 29% to 42%** ([Emond et al, 1980](#)). Two retrospective analyses—the Nationwide Inpatient Sample (NIS) and the Nationwide Emergency Department Sample—provide estimates of the incidence of priapism in the United States. [Chrouser and colleagues \(2011\)](#) accessed data from the NIS (1998 to 2006); the NIS database extrapolation suggests that 1868 to 2960 patients with priapism are admitted annually to hospitals in the United States. In the actual sample (4237 hospitalizations), 30% of patients were white, 61.1% were black, and 6.3% were Hispanic; 41.9% of patients had a diagnosis of SCD; and 36.2% of patients required penile surgery. The mean age at time of hospital admission for priapism associated with SCD was 23.8 years and for non-SCD was 40.8 years. [Roghamann and colleagues \(2013\)](#) looked at the Nationwide Emergency Department Sample. They estimated that from 2006 to 2009 there were 32,462 emergency department visits for priapism. The number of emergency department visits for priapism in the United States was higher during summer, and 13.3% of patients were admitted to the hospital.

In 1986 Pohl and colleagues reported on 230 cases. The cause of priapism was identified as idiopathic in the majority; 21% of cases were associated with alcohol or drug use or abuse, 12% with perineal trauma, and 11% with SCD ([Pohl et al, 1986](#)). Although SCD is a predominant cause of veno-occlusive priapism in the literature, there is a wide variety of reported associations from urinary retention to insect bites ([Hoover and Fortenberry, 2004](#)). Priapism has even been reported after spider bites and envenomation from the Brazilian banana spider, *Phoneutria nigriventer* ([Andrade et al, 2008](#); [Villanova et al, 2009](#)). The genus *Phoneutria* (from the Greek for “murderess”) has eight species. *P. nigriventer* is known to hide in dark and moist places, wander the jungle floor, and stow away within banana shipments. *P. nigriventer* is blamed for most cases of envenomation in Brazil; the venom contains a neurotoxin that has calcium channel blocking properties, inhibits glutamate release, and inhibits calcium reuptake and glutamate reuptake. Bites can cause intense pain, loss of muscle control—paralysis, breathing problems—asphyxiation, and priapism. Two peptides isolated from the venom of *P. nigriventer* have been directly linked with the induction of persistent and painful erections in mammals (Tx2-5 and Tx2-6) ([Leite et al, 2012](#)). The protein has been named *eretina* and has been shown to have a highly specific interference at the molecular level with the nitric oxide pathway (NO). Penile erection has been induced in vivo with *eretina* by direct intraperitoneal injection with a minimum effective dose of 0.006 µg/kg ([Andrade et al, 2008](#)).

Hematologic dyscrasias are a major risk factor for ischemic priapism. Priapism has been described as a complication of SCD, thalassemia, hereditary spherocytosis, paroxysmal nocturnal hemoglobinuria, glucose-6-phosphate dehydrogenase deficiency, glucose-6-phosphate isomerase deficiency, and congenital dyserythropoietic anemia ([Burnett, 2005](#); [Kato, 2012](#)). **Thrombotic disease states have also been cited as precipitants of ischemic priapism;** these conditions include asplenia, erythropoietin use, hemodialysis with heparin use, and cessation of Coumadin therapy. Intracavernous heparin given as a therapy for priapism caused by rebound hypercoagulable states has actually worsened the condition ([Fassbinder et al, 1976](#); [Bschleipfer et al, 2001](#)). Priapism may occur in patients with excessive white blood cell (WBC) counts. The incidence of priapism in adult male patients with leukemia is 1% to 5% ([Chang et al, 2003](#)). Hyperleukocytosis causes priapism in these patients; it

is believed that mechanical pressure on abdominal veins secondary to splenomegaly causes congestion of cavernous outflow and sludging of leukemic cells within the CC. When priapism occurs in the oncology setting, evaluation and management of the predisposing condition must accompany interventions directed at the penis. In hematologic malignancies, leukapheresis and cytotoxic therapy (hydroxyurea, cytosine arabinoside) may reduce the numbers of circulating WBCs ([Ponniah et al, 2004](#); [Manuel et al, 2007](#)). **Priapism secondary to metastatic infiltrating solid lesions rather than leukemoid reaction is extremely rare.** In most case reports of metastatic priapism, the primary malignancy is genitourinary (prostate and bladder). Metastatic infiltration of the penis may proceed with solid replacement or focal deposits within the CC, glans, and corpus spongiosum. Theoretically, metastatic deposits within the corpora could obstruct venous outflow, resulting in ischemic priapism. Depending on the status of the patient, metastatic lesions may be managed expectantly, with partial or total penectomy, chemotherapy, or irradiation. These cases are too rarely and poorly described to define best practice recommendations ([Robey and Schellhammer, 1984](#); [Chan et al, 1998](#); [Guvel et al, 2003](#); [Celma Doménech et al, 2008](#)) (Box 28-1).

Sickle Cell Disease

Blood dyscrasias are a risk factor for ischemic priapism. SCD priapism has traditionally been ascribed to stagnation of blood within the sinusoids of the CC during physiologic erection, secondary to obstruction of venous outflow by sickled erythrocytes ([Lue, 2002](#)). [Nelson and Winter \(1977\)](#) described a series of cases in which SCD was the primary cause of ischemic priapism in 23% of adults and 63% of children. **Sickle cell hemoglobinopathy accounts for at least a third of all cases of priapism,** and, indeed, prevalence of ischemic priapism varies significantly within the population of males in a community with SCD. From [Emond and colleagues' 1980](#) observational study comes the most commonly quoted incidence: Among 104 men attending an outpatient sickle cell clinic in Kingston, Jamaica, the incidence of priapism in men with homozygous sickle cell (SS) disease was 42% ([Emond et al, 1980](#)). In a U.S. clinical series, [Tarry and associates \(1987\)](#) found that 6.4% of male children in an outpatient sickle cell clinic had a history of priapism. [Adeyoju and colleagues \(2002\)](#), in an international multicenter observational study of SCD, mailed or interviewed 130 patients attending SCD clinics in the United Kingdom and Nigeria. Respondents ranged in age from 4 to 66 years old, with a mean age of 25. The authors cited mean age of onset of priapism as 15 years, with 75% of patients having their first episode before age 20 and rare first-time presentations by the third decade of life. In the questionnaires a clear distinction was made between acute severe prolonged priapism lasting longer than 24 hours requiring emergency attention and stuttering recurrent priapism of shorter and self-limiting duration. In this population the incidence of acute priapism was 35%; of these patients, 72% gave a history of stuttering priapism. The median frequency of occurrence of stuttering priapism was three times per month; the median duration of each episode was 1.2 hours, with the longest being 8 hours. Precipitating events reported from greatest to least were sexual arousal or intercourse, fever, sleep, cold weather, and dehydration. Self-administered regimens were analgesics, drinking water, and exercise. Twenty-one percent of patients reporting a history of priapism also reported ED. Only 7% of young men who had not experienced priapism were even aware that priapism was a potential complication of their SCD. On the basis of the World Health Organization global prevalence map of SCD, [Aliyu and colleagues \(2008\)](#) estimated that 20 to 25 million individuals worldwide have homozygous SCD: 12 to 15 million in sub-Saharan Africa, 5 to 10 million in India, and 3 million in other world regions. They also found that 70,000 patients with SCD live in the United States ([Aliyu et al, 2008](#)).

The sickle cell genetic mutation is the result of a single amino acid substitution in the β -globin subunit of hemoglobin S (HbS). The clinical features are seen in homozygous SCD patients: chronic hemolysis, vascular occlusion, tissue ischemia, and

Prazosin, terazosin, doxazosin, tamsulosin

ANTI-ANXIETY AGENT

Hydroxyzine

ANTICOAGULANTS

Heparin, warfarin

ANTIDEPRESSANTS AND ANTIPSYCHOTICS

Trazodone, bupropion, fluoxetine, sertraline, lithium, clozapine, risperidone, olanzapine, chlorpromazine, thioridazine, phenothiazines

ANTI-HYPERTENSIVES

Hydralazine, guanethidine, propranolol

ATTENTION-DEFICIT/HYPERACTIVITY DISORDER AGENTSMethylphenidates (Concerta, Daytrana, Focalin, Metadate, Methylin, Quillivant, Ritalin)
Atomoxetine (Strattera)**RECREATIONAL DRUGS**

Alcohol, cocaine (intranasal and topical), crack cocaine, marijuana

GENITOURINARY CONDITIONS

Straddle injury, coital injury, pelvic trauma, kick to penis or perineum, arteriovenous or arteriocavernous bypass surgery, urinary retention

HEMATOLOGIC DYSCRASIAS

Sickle cell disease, thalassemia, granulocytic leukemia, myeloid leukemia, lymphocytic leukemia, multiple myeloma, hemoglobin Olmsted variant, fat emboli associated with hyperalimentation, hemodialysis, glucose-6-phosphate dehydrogenase deficiency

HORMONES

Gonadotropin-releasing hormone, testosterone

INFECTIOUS (TOXIN-MEDIATED) CAUSES

Scorpion sting, spider bite, rabies, malaria

METABOLIC CONDITIONS

Amyloidosis, Fabry disease, gout

NEOPLASTIC CAUSES (METASTATIC OR REGIONAL INFILTRATION)

Prostate, urethra, testis, bladder, rectum, lung, kidney

NEUROGENIC CONDITIONS

Syphilis, spinal cord injury, cauda equina compression, autonomic neuropathy, lumbar disk herniation, spinal stenosis, cerebral vascular accident, brain tumor, spinal anesthesia, cauda equina syndrome

VASOACTIVE ERECTILE AGENTSPapaverine, phentolamine, prostaglandin E₁, oral phosphodiesterase type 5 inhibitors, combination intracavernous therapy

Modified from Lue TF. Physiology of penile erection and pathophysiology of erectile dysfunction and priapism. In: Walsh PC, Retik AB, Vaughan ED, et al, editors. Campbell's urology. Philadelphia: Saunders; 2002. p. 1610–96.

end-organ damage. HbS polymerizes when deoxygenated, injuring the sickle erythrocyte, activating a cascade of hemolysis and vaso-occlusion. Membrane damage results in dense sickling of red cells, causing adhesive interactions among sickle cells, endothelial cells, and leukocytes. Hemolysis releases hemoglobin into the plasma. Free hemoglobin reacts with NO to produce methemoglobin and nitrate. This is a scavenging reaction; the vasodilator NO is oxidized to inert nitrate. Sickled erythrocytes release arginase-I into blood plasma, which converts L-arginine into ornithine, effectively removing substrate for NO synthesis. Oxidant radicals further reduce NO bioavailability. The combined effects of NO scavenging and arginine catabolism result in a state of NO resistance and insufficiency termed *hemolysis-associated endothelial dysfunction* (Morris et al, 2005; Rother et al, 2005; Kato et al, 2007; Aliyu et al, 2008).

Contemporary science implicates hemolysis and reduced NO in the pathogenesis of pulmonary hypertension, leg ulcers, priapism, and stroke in SCD patients, whereas increased blood viscosity is believed to be responsible for painful crises, osteonecrosis, and acute chest syndrome (Kato, 2012; Kato et al, 2006). SCD patients with priapism have a fivefold greater risk of developing pulmonary hypertension. SCD priapism is also associated with reduced hemoglobin levels and increased hemolytic markers: reticulocyte count, bilirubin, lactate dehydrogenase, and aspartate aminotransferase. Cerebral vascular accidents are more frequent, close to episodes of full-blown priapism; the ASPEN syndrome (association of SCD, priapism, exchange transfusion, and neurologic events) describes cerebral vascular accidents in SCD patients who have received exchange transfusions (Siegel et al, 1993; Merritt et al, 2006). Sickle cell trait is considered a benign condition; a few complications have been associated with

extreme physical exertion. There have been case reports of sickle cell trait as the predisposing factor to ischemic priapism (Larocque and Cosgrove, 1974; Birnbaum and Pinzone, 2008).

Iatrogenic Priapism: Intracavernous Injections

Prolonged erection is more commonly reported than is priapism after therapeutic or diagnostic injection of intracavernous vasoactive medications (Broderick and Lue, 2002). Despite the introduction of effective oral medications for ED in 1998, intracavernous injection (ICI) remains an important therapeutic option for men with severe ED in whom a phosphodiesterase type 5 (PDE5) inhibitor fails or who cannot take PDE5 inhibitors because they require or include nitrates. In many communities patients receiving intracavernous medications for ED will outnumber patients with SCD. Priapism after ICI is a problem all urologists will encounter and must be prepared to manage. In a review of worldwide reports on ICI programs, Junemann and colleagues (1990) noted that diagnostic injection resulted in 5.3% of men getting ischemic priapism, and 0.4% of men reported priapism after injecting at home. In papaverine-based ICI programs, reports of prolonged erections and priapism are poorly distinguished and range from 0% to 35% (Broderick and Lue, 2002). In worldwide clinical trials of the Alprostadil Study Group, prolonged erection (defined as 4 to 6 hours) was described in 5% of patients, and priapism (longer than 6 hours) in 1% (Porst, 1996). In the United States the approved label and package insert for one product (alprostadil [Caverject]) cites the frequency of prolonged erection (4 to 6 hours) as 4% and frequency of priapism as 0.4%. The label recommends that “to minimize chances of prolonged erection or priapism Caverject

should be titrated slowly to the lowest effective dosage." In papaverine/phentolamine/alprostadil ICI programs, prolonged erections have been reported in 5% to 35% of patients (Broderick and Lue, 2002).

Idiopathic Priapism: Oral Phosphodiesterase Type 5 Inhibitors and Medications for Attention-Deficit/Hyperactivity Disorder

All PDE5 inhibitors have similar side effects related directly to their mode of action, tissue content of substrate, and pharmacologic selectivity for type 5 inhibition versus other phosphodiesterase enzymes. Side effects occurring in 2% or more of patients include headache, flushing, dyspepsia, rhinitis, light sensitivity, and myalgia. Morales and colleagues (1998) analyzed data from 4274 men who received double-blind treatment with sildenafil or placebo for up to 6 months and 2199 who received long-term open-label sildenafil for up to 1 year. No cases of priapism (erection lasting longer than 4 hours) were reported. No cases of priapism were reported by Montorsi and colleagues (2004) in a multicenter, open-label, 24-month extension of 8- or 12-week double-blind, placebo-controlled studies assessing the long-term efficacy, safety, and tolerability of tadalafil in 1173 men with ED. Nonetheless, the indications and usage section of the U.S. Food and Drug Administration (FDA)-approved product labeling (U.S. prescribing information [USPI]) for PDE5 inhibitors does contain this warning: "There have been rare reports of prolonged erection greater than 4 hours and priapism (painful erections >6 hours duration) for this class of compounds." Both the USPI and European Summary of Product Characteristics label information contain warning or precautionary language about the use of these agents in men who have conditions predisposing them to priapism. The FDA approved Cialis (tadalafil) as an oral treatment for ED (2.5 mg, 5 mg, 10 mg, and 20 mg) in 2003. Once-daily tadalafil (2.5 mg and 5 mg) was approved for oral treatment of ED in 2008, and subsequently in 2011 tadalafil (2.5 mg and 5 mg) was approved for the signs and symptoms of benign prostatic hyperplasia (BPH) and treatment of ED. Tadalafil 5 mg daily caused no priapism in a phase 2 clinical study of 281 men with history of lower urinary tract symptoms secondary to BPH for 6 weeks, followed by dosage escalation to 20 mg once daily for 6 weeks (McVary et al, 2007). The 2013 label for the most recently approved PDE5 inhibitor, Stendra (avanafil 50 mg, 100 mg, 200 mg), contains virtually identical precautionary wording as prior labels for as-needed (PRN) oral forms of sildenafil, vardenafil, and tadalafil: "There have been rare reports of prolonged erection greater than 4 hours and priapism (painful erections greater than 6 hours)."

From 1999 to 2007 there were at least nine case-based reports of oral PDE5 inhibitor use and adult priapism and at least one pediatric patient (Aoyagi et al, 1999; Kassim et al, 2000; Sur and Kane, 2000; Goldmeier, 2002; McMahon, 2003; Wilt and Fink, 2004; Galatti et al, 2005; King et al, 2005; Kumar, et al 2005; and Wills et al, 2007). Most case reports detailing priapism after use of a PDE5 inhibitor reveal histories of increased risk for priapism: SCD, spinal cord injury, use of a PDE5 inhibitor recreationally, use of a PDE5 inhibitor in combination with ICI, history of penile trauma, use of psychotropic medications, or use of recreational drugs. Wills and coworkers (2007) described a 19-month-old boy weighing 10 kg who accidentally ingested up to six tablets of sildenafil 50 mg. The child had persistent sinus tachycardia and partial erection for 24 hours; the authors presume this was a high-flow priapism (HFP) because the shaft was neither completely rigid nor painful. Erection in the child subsided spontaneously after overnight intravenous hydration and observation.

In 2013 the FDA issued a warning that methylphenidate medications used in the treatment of attention-deficit/hyperactivity disorder (ADHD) may result in prolonged erection or priapism. The FDA also warns that atomoxetine, another ADHD drug, has been linked to reports of priapism in children, teens, and adults. Drug therapy in ADHD is used in children, adolescents, and adults

to increase the ability to pay attention and decrease impulsiveness and hyperactivity. The 2012 Summary Health Statistics for U.S. Children: National Health Interview Survey (Bloom et al, 2013) estimated that more than 6.4 million children ages 4 to 17 have been diagnosed with ADHD; this represents a 41% increase over a decade. The Centers for Disease Control and Prevention (CDC) further estimate that two thirds of these children are prescribed methylphenidate medications (Centers for Disease Control and Prevention, 2013).

Methylphenidate is a central nervous system stimulant; atomoxetine is a selective norepinephrine reuptake inhibitor. The FDA cautions that physicians may be tempted to switch patients from methylphenidate medications to atomoxetine but that priapism is actually more common in patients taking atomoxetine (U.S. Food and Drug Administration, 2013). The median age of male patients taking methylphenidate who developed priapism (erection lasting longer than 4 hours) was 12.5 years.

KEY POINTS: ISCHEMIC PRIAPISM AS A COMPLICATION OF ERECTILE DYSFUNCTION THERAPY

- Prolonged erection is more commonly reported than priapism after therapeutic or diagnostic injection of intracavernous vasoactive medications.
- In worldwide clinical trials of alprostadil, prolonged erection (defined as 4 to 6 hours) occurred in 5% of administrations, and priapism (longer than 6 hours) in 1%.
- In clinical practice, ICI of Trimix (papaverine, phentolamine, and alprostadil) results in prolonged erections in 5% to 35% of administrations.
- Few case reports have documented priapism after PDE5 inhibitor therapy. These reports suggest that men were at increased risk for priapism because of SCD, spinal cord injury, use of a PDE5 inhibitor recreationally, use of a PDE5 inhibitor in combination with ICI, history of penile trauma, use of psychotropic medications, or abuse of narcotics.
- Methylphenidate medications and atomoxetine used in the treatment of ADHD may result in prolonged erection or priapism.

Etiology of Stuttering (Intermittent) Priapism

Stuttering (intermittent) priapism describes a pattern of recurrent priapism. The term has traditionally been used to describe recurrent unwanted and painful erections in men with SCD. Patients typically awaken with an erection that persists up to 4 hours and becomes progressively painful secondary to ischemia. SCD patients may experience stuttering priapism from childhood. Any patient who has experienced ischemic priapism is at risk for stuttering priapism. Patients with stuttering priapism will experience repeated painful intermittent attacks up to several hours before remission. Affected young men suffer embarrassment, sleep deprivation, and performance anxiety with sexual partners (Chow and Payne, 2008). In a study of 130 patients with SCD, Adeyoku and colleagues (2002) reported that 46 (35%) had a history of priapism and, of these, 33 (72%) had a history of stuttering priapism. In 75% of patients the first episode of stuttering priapism occurred before the age of 20. Two thirds of males with SCD ischemic priapism at presentation will describe prior stuttering attacks (Jesus and Dekermacher, 2009). Commonly reported precipitants of full-blown SCD priapism are stuttering nocturnal or early morning erections, dehydration, fever, and exposure to cold (Broderick, 2012).

Etiology and Pathophysiology of Nonischemic (Arterial, High-Flow) Priapism

HFP is a persistent erection caused by unregulated cavernous arterial inflow. The epidemiologic data on nonischemic priapism is almost

exclusively derived from small case series or individual case reports. Nonischemic priapism is much rarer than ischemic priapism, and the cause is largely attributed to trauma. Forces may be blunt or penetrating, resulting in laceration of the cavernous artery or one of its branches within the corpora. The cause most commonly reported is a straddle injury to the crura. Other mechanisms include coital trauma, kicks to the penis or perineum, pelvic fractures, birth canal trauma to the newborn male, needle lacerations, complications of penile diagnostics, and vascular erosions complicating metastatic infiltration of the corpora (Witt et al, 1990; Brock et al, 1993; Dubocq et al, 1998; Burgu et al, 2007; Jesus and Dekermacher, 2009). Although accidental blunt trauma is the most common cause, HFP has been described after iatrogenic injury from cold-knife urethrotomy, Nesbitt corporoplasty, and deep dorsal vein arterialization (Wolf and Lue, 1992; Liguori et al, 2005). Any mechanism that lacerates a cavernous artery or arteriole can produce unregulated pooling of blood in sinusoidal space with consequent erection. Nonischemic priapism is typically delayed in onset compared with the episode of blunt trauma (Ricciardi et al, 1993). Sustained partial erection may develop 24 hours after perineal or penile blunt trauma. It is believed that the hemodynamics of a nocturnal erection disrupts the clot and the damaged artery or arteriole ruptures; the unregulated arterial inflow creates a sinusoidal fistula. As healing progresses with clearing of clot and necrotic smooth muscle tissue, the fistula forms a pseudocapsule. Formation of a pseudocapsule at the site of fistula may take several weeks to months.

Contemporary reports suggest that HFP may have a unique subvariety. Several authors have noted that after either aggressive medical management of ischemic priapism or surgical shunting, priapism may rapidly recur with conversion from ischemia to high flow. HFP has been reported after aspiration and injection of α -adrenergics in the management of ischemic priapism (McMahon, 2002; Rodriguez et al, 2006; Bertolotto et al, 2009). Color Doppler ultrasonography (CDU) has shown formation of an arteriolar-sinusoidal fistula at the site of intervention (needle laceration or shunt site) (Fig. 28-2). On rare occasions after reversal of ischemic priapism, a new high-flow hemodynamic state of the cavernous arteries occurs with no evidence of fistula. This presentation of HFP should be suspected in patients in whom rapid recurrence, persistence of erection with partial penile rigidity, or stuttering priapism not associated with pain is evident. Nonfistula type of arterial priapism is the result of dysregulation of cavernous inflows. Nonfistula arterial priapism is a rare complication after management of ischemic priapism (Seftel et al, 1998; Cruz Guerra et al, 2004; Wallis et al, 2009). Penile tenderness to palpation is easily confused with the ongoing ache of persistent ischemia. Soft-tissue edema and ecchymosis render the physical examination findings equivocal after medical and surgical maneuvers to alleviate priapism. Dysregulated arterial inflows with or without a fistula can best be distinguished from persistent ischemic priapism by CDU.

KEY POINTS: HIGH-FLOW PRIAPISM

- Nonischemic priapism is much rarer than ischemic priapism.
- HFP results from laceration or disruption of a cavernous artery or arteriole.
- The most common cause is a straddle injury to the crura.
- Other mechanisms include coital trauma, kicks to the penis or perineum, pelvic fractures, birth canal trauma to the male newborn, needle lacerations, complications of penile diagnostics, and vascular erosions complicating metastatic infiltration of the corpora.
- HFP has been described after iatrogenic trauma from cold-knife urethrotomy, corporoplasty, and penile revascularization procedures.

Priapism in Children

Priapism in children and adolescents is most commonly related to SCD. The literature suggests that the incidence of priapism in pediatric sickle cell clinics is 2% to 6% (Tarry et al, 1987; Jesus and Dekermacher, 2009). The majority of SCD priapism is ischemic. In the newborn period, fetal hemoglobin predominates, not HbS (Burgu et al, 2007). SCD phenotypes related to ischemic or occlusive crises are unlikely to be evident while fetal hemoglobin persists. Newborn priapism is an extremely rare phenomenon with only limited case reports and rare application of contemporary diagnostic modalities. Erection is frequently elicited in males during the newborn period. In male newborns, simple tactile stimulation such as diaper changing, bathing, and urethral catheterization may result in erection; the erection quickly subsides after cessation of stimuli. Fewer than 20 cases of newborn priapism have been reported in the literature, and rarely has the cause been defined; causes have included polycythemia, blood transfusion, and birth canal trauma (Amlie et al, 1977; Leal et al, 1978; Shapiro, 1979; Walker and Casale, 1997). The majority of cases have been conservatively managed with spontaneous resolution reported from hours to days. Minimally invasive diagnostics (CDU) should be performed (Pietras et al, 1979; Meijer and Bakker, 2003). In children who develop priapism after straddle trauma, every effort should be made to localize the arteriolar-sinusoidal fistula. Hatzichristou and colleagues (2002) reported that identification of the fistula by Doppler ultrasound coupled with direct manual compression softens the high-flow erection and may speed spontaneous resolution. They suggested that this noninvasive therapy likely works in children and not adults because the perineum has considerably less subcutaneous fat and because crural bodies are more easily compressed.

MOLECULAR BASIS OF ISCHEMIC AND STUTTERING PRIAPISM

Advances in our understanding of the molecular basis of priapism have drawn significantly from both in vitro and in vivo experimental studies using animal models. Data on the true inciting mechanisms involved in ischemic priapism are emerging. Ischemic priapism consists of an imbalance of vasoconstrictive and vasorelaxatory mechanisms predisposing the penis to hypoxia and acidosis. In vitro studies have demonstrated that when corporal smooth muscle strips and cultured corporal smooth muscle cells are exposed to hypoxic conditions, α -adrenergic stimulation fails to induce corporal smooth muscle contraction (Broderick and Harkaway, 1994; Saenz de Tejada et al, 1997; Muneer et al, 2005). Extended periods of severe anoxia significantly impair corporal smooth muscle contractility and cause significant apoptosis of smooth muscle cells and, ultimately, fibrosis of the CC.

In experimental animal models of ischemic priapism, lipid peroxidation, an indicator of injury induced by reactive oxygen species (ROSs), and increased hemo-oxygenase expression occur in the penis during and after ischemic priapism (Munarriz et al, 2003; Jin et al, 2008). Additional pathophysiologic mechanisms involved in the progression of ischemia-induced fibrosis are the upregulation of hypoxia-induced growth factors. Transforming growth factor- β (TGF- β) is a cytokine that is vital to tissue repair. However, excess amounts may induce tissue damage and scarring. Upregulation of TGF- β occurs during hypoxia and in response to oxidative stress (Moreland et al, 1995; Jin et al, 2008). It is hypothesized that TGF- β may be involved in the progression of the corporal smooth muscle to fibrosis (Bivalacqua et al, 2000; Jeong et al, 2004).

Transgenic mouse models of SCD manifest priapism (Beuzard, 1996; Bivalacqua et al, 2009b). There have been two major discoveries in elucidation of the molecular mechanism of ischemic priapism. Mi and colleagues (2008) have shown that transgenic sickle cell mice CC have enhanced smooth muscle relaxation to electrical field stimulation. Transgenic sickle cell mice and mice lacking endothelial NO synthase (eNOS) gene expression display

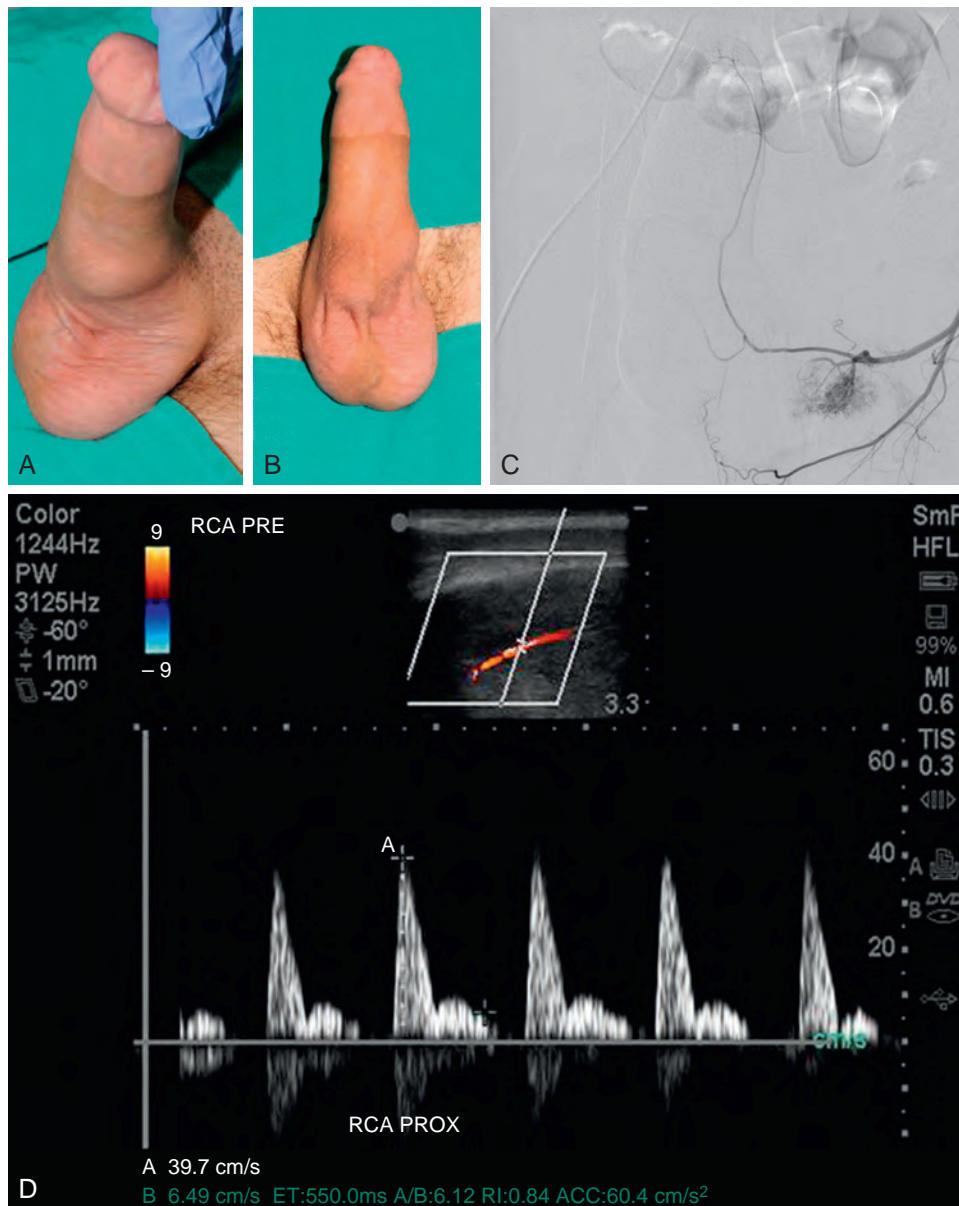

Figure 28-2. A, A 21-year-old white man with a history of ischemic priapism after binging with alcohol, marijuana, and energy drinks. Patient had a series of penile shunt procedures in attempts to reverse ischemic priapism: Winter, Al-Ghorab, bilateral corpora cavernosa to spongiosum. Six months later he sought evaluation for embarrassing persistent partial erection; consistent with converting from ischemic to high-flow priapism, he had no pain. A, Tumescent shaft with glans scar. B, Penoscrotal bulging at site of cavernospongiosal shunts. C, Angiogram of fistula originating at the bulbourethral artery. D, Doppler flows with peak systolic velocity of 39 cm/sec and 6 cm/sec; end diastolic flow and resistive index, 84.

supraphysiologic erections and spontaneously phasic priapic activity in vivo (Bivalacqua et al, 2006, 2007).

Endothelial cells actively regulate basal vascular tone and vascular reactivity by responding to mechanical forces and neuro-humoral mediators with the release of a variety of relaxing and contracting factors. In the penis the vascular endothelium is a source of vasorelaxing factors such as NO and adenosine, as well as vasoconstrictor factors such as RhoA/Rho-kinase. Recent evidence suggests that in states of priapism there may be aberrant NO and adenosine signaling, thus identifying a potential role for NO/cyclic guanosine monophosphate (cGMP), as well as adenosine and RhoA/Rho-kinase signaling in the pathophysiology of ischemic priapism (Champion et al, 2005; Mi et al, 2008; Bivalacqua et al, 2009a).

eNOS^{-/-} mutant mice have an exaggerated erectile response to cavernous nerve stimulation and have phenotypic changes in erectile function consistent with priapism (Champion et al, 2005; Bivalacqua et al, 2006). Mice lacking the *eNOS* gene manifest a priapism phenotype through mechanisms involving defective PDE5 regulatory function in the penis, resulting from altered endothelial NO/cGMP signaling in the organ (Lin et al, 2003; Bivalacqua et al, 2006). Supporting this hypothesis, PDE5 expression is significantly reduced in corpora cavernosa smooth muscle cells (CCSMCs) grown under anoxic and hypoxic cell culture conditions (Lin et al, 2003). In the context of molecular dysregulation, the cyclic nucleotide cGMP is produced in low steady-state amounts under the influence of priapism-related destruction of the vascular endothelium and thus reduced endothelial NO activity; this

situation downregulates the set point of PDE5 function, secondary to altered cGMP-dependent feedback control mechanisms (Champion et al, 2005; Bivalacqua et al, 2006; Burnett and Bivalacqua, 2007). When NO is neuronally produced in response to an erectogenic stimulus or with nocturnal erections, cGMP production surges in a manner that leads to excessive erectile tissue relaxation because of basally insufficient PDE5 enzyme to degrade the cyclic nucleotide. In addition, reduced Rho-kinase activity (contractile mediator) may contribute to the susceptibility of corporal tissue to excessive relaxation via two distinct molecular mechanisms. Two distinct molecular mechanisms appear to act in concert to promote stuttering ischemic priapism: enhanced vasorelaxation by uninhibited cGMP and diminished contractile effects of Rho-kinase. Transgenic sickle cell mice also have significant reductions in penile NO/cGMP signaling leading to deficient PDE5 expression and activity, as well as reduced RhoA/Rho-kinase expression, which causes them to manifest enhanced erectile responses and recurrent priapism (Champion et al, 2005). Another potential cause of enhanced corporal smooth muscle relaxation in SCD-associated priapism is elevated penile adenosine levels, which cause the CC to be in a chronically vasodilated state (Mi et al, 2008). Taken together, these data suggest that ischemic priapism and, most important, stuttering priapism are direct results of NO imbalance resulting in aberrant molecular signaling, PDE5 dysregulation, adenosine overproduction, and reductions in Rho-kinase activity, translating into enhanced corporal smooth muscle relaxation and inhibition of vasoconstriction in the penis.

KEY POINTS: SICKLE CELL DISEASE AND PRIAPISM

- Sickle cell hemoglobinopathy accounts for at least a third of all cases of ischemic priapism.
- The sickle cell genetic mutation is the result of a single amino acid substitution in the β -globin subunit of hemoglobin.
- Clinical features are seen in homozygous SCD patients: chronic hemolysis, vascular occlusion, tissue ischemia, and end-organ damage.
- Hemolysis and reduced NO are central in the pathogenesis of pulmonary hypertension, leg ulcers, priapism, and stroke in SCD patients.
- Increased blood viscosity is responsible for painful crises, osteonecrosis, and acute chest syndrome.
- SCD patients may experience stuttering priapism from childhood.
- SCD patients with stuttering priapism will experience repeated painful intermittent attacks up to several hours before remission.
- Stuttering priapism in SCD is the result of molecular dysregulation with enhanced corporal smooth muscle vasorelaxing forces and inhibition of vasocontractile forces in the penis.

EVALUATION AND DIAGNOSIS OF PRIAPISM

History

In order to initiate appropriate management, the physician must determine whether the underlying priapism hemodynamics are ischemic or nonischemic. **Emergency management of ischemic priapism is recommended.** Ischemia should be suspected when the patient has progressive penile pain associated with the duration of erection; has used a known drug associated with priapism; has SCD or another blood dyscrasia; or has a known neurologic condition, especially those affecting the spinal cord. Stuttering priapism history is one of recurrent episodes of prolonged erections, usually nonresolving morning erections. **Nonischemic priapism should be**

BOX 28-2 Elements in Taking the History of Priapism

Duration of erection
 Presence of pain
 Previous episodes of priapism and method of treatment
 Baseline erectile function
 Use of any erectogenic therapies (both prescription and nutritional supplements)
 Medications and recreational drugs
 Sickle cell disease, hemoglobinopathies, hypercoagulable states
 Trauma to the pelvis, perineum, or penis

suspected when there is no pain and the erection duration has not been accompanied by progressive discomfort. There is a history of straddle injury, coital trauma, blunt trauma to the penis or perineum, penile injection, penile surgery, or a diagnostic procedure of the pelvic and penile vessels. The onset of post-traumatic HFP in adults and children may be delayed by hours to several days after the initial injury (Box 28-2).

Physical Examination

Inspection and palpation of the penis are recommended to determine the extent and degree of tumescence and rigidity; the involvement of the cavernous bodies; the presence of pain; and the evidence of trauma to the perineum. **In ischemic priapism the corporal bodies will be completely rigid; the glans penis and corpus spongiosum are not.** Although malignancies rarely cause priapism, examination of the abdomen, testicles, perineum, rectum, and prostate may help identify a primary cancer. Malignant infiltration of the penis causes indurated nodules within or replacing corporal tissue. The subtle differences in the penile examination findings may be apparent to the experienced urologist but can be overlooked by emergency personnel on initial evaluation (Fig. 28-3A to F). If physical examination reveals the penis to be nontender, tumescent, or partially erect, nonischemic priapism should be suspected. **In nonischemic priapism the corpora will be tumescent but not completely rigid.** In children and adults with HFP, depending on the location of trauma and time since the traumatic event, there may be residual bruising at the perineum from straddle injury (Table 28-1).

Laboratory Testing

Evaluation should include a complete blood count (CBC), WBC count with blood cell differential, platelet count, and coagulation profile to assess anemia, rule out infection, detect hematologic abnormalities, and ensure that the patient can safely tolerate surgical interventions should initial medical management fail. In African-Americans, a sickle cell preparation and hemoglobin electrophoresis should be requested. Other hematologic abnormalities may cause priapism, including leukemia, platelet abnormalities, and thalassemia, and these should be sought if the cause is not evident. An elevated reticulocyte count is nonspecific and may be present in both priapism caused by SCD and thalassemia. Urine and serum toxicology panels should be done if recreational narcotic or prescription psychoactive drugs are suspected from the history. A corporal blood gas by aspiration is recommended in the emergency evaluation of priapism. The corporal blood aspirate differentiates ischemic from nonischemic priapism. Aspiration may be both diagnostic and therapeutic. Visual inspection of the color and consistency of an initial penile aspirate will reveal dark deoxygenated blood with a "crankcase oil" appearance in ischemic priapism. The initial corporal aspirate may be sent for blood gas testing to document pH, PO₂, and PCO₂ (Table 28-2). CDU should be initiated if the history

Figure 28-3. A, Sagittal magnetic resonance imaging (MRI) scan of the penis showing metastatic deposits of prostate cancer to the corpus cavernosum. B, Coronal MRI image from the same patient. Note the proximal and distal metastatic deposits of prostate cancer. C, T2-weighted MRI showing chondrosarcoma replacing corpus cavernosum. D to F, A 50-year-old white man with neurofibromatosis with a 6- to 12-month history of partial erection and progressive penile deformity. He was referred with a diagnosis of Peyronie disease. Penile biopsies showed malignant peripheral nerve sheath tumor or neurofibrosarcoma. T2- and T1-weighted MRI images show large irregular masses replacing corpora cavernosa. G, Color Doppler imaging shows irregular right cavernous artery with high flow. (C, Courtesy David Ralph.)

suggests penile or perineal trauma or if the corporal aspirate reveals well-oxygenated blood (Fig. 28-4).

Penile Imaging

CDU of the penis and perineum is recommended in the evaluation of priapism. CDU is an adjunct to the corporal aspirate

TABLE 28-1 Key Findings in Priapism

FINDINGS	ISCHEMIC PRIAPISM	NONISCHEMIC PRIAPISM
Perineal trauma	Seldom	Usually
Hematologic abnormalities	Usually	Seldom
Recent intracorporal injection	Sometimes	Sometimes
Corpora cavernosa fully rigid	Usually	Seldom
Penile pain	Usually	Seldom
Abnormal penile blood gas	Usually	Seldom
Cavernous inflow (on Doppler)	Seldom	Usually

in differentiating ischemic from nonischemic priapism. Patients with prolonged ischemic priapism will have no blood flow in the cavernous arteries; the return of the cavernous artery waveform will accompany successful detumescence. Patients with nonischemic priapism have normal to high blood flow velocities detectable in the cavernous arteries; an effort should be made to localize the characteristic blush of color emanating from the disrupted cavernous artery or arteriole (Broderick and Lue, 2002). Examination of the entire penile shaft and perineum is recommended; this can be done with the patient supine but frog-legged (Fig. 28-5). Penile arteriography should be reserved for the management of HFP, when embolization is planned; arteriography is too invasive as a diagnostic procedure to differentiate ischemic from nonischemic priapism (Burnett, 2004). The data from penile blood gas assessments become confusing after interventions. CDU should always be considered in the evaluation of a full or partial erection after treatments for ischemic priapism. The differential diagnosis includes resolved ischemia with penile edema, persistent ischemia, and conversion to high-flow state. Chiou and colleagues (2009a) have recommended that to accurately categorize presentations as nonischemic or ischemic, careful interpretation of CDU hemodynamics must be done in conjunction with the clinical assessment. They describe eight patients with priapism after ICI (duration ≤7 hours), all of whom showed presence of cavernous arterial inflows with varied peak systolic velocities and end-diastolic velocities. They concluded that most patients with priapism after ICI (and duration <7 hours) have a hemodynamic picture of mixed arteriogenic and veno-occlusive priapism. In their series, men with idiopathic ischemic priapism longer than 20 hours showed no detectible cavernous arterial inflows.

There have recently been reports on the use of magnetic resonance imaging (MRI) in priapism. Kirkham and colleagues (2008) noted that there are three possible roles for MRI to help in the assessment of priapism; the primary role would be in the imaging of a well-established arteriolar-sinusoidal fistula. The authors acknowledge that a limitation of MRI is resolution; MRI cannot demonstrate small vessels as clearly as high-frequency Doppler sonography or angiography. The second role would be in ischemic priapism to demonstrate the presence and extent of tissue thrombus and corporal smooth muscle infarction. Ralph and coworkers (2009) used MRI to assess 50 patients presenting with refractory ischemic priapism. All patients had priapism lasting from 24 to 72

Figure 28-4. A, The initial corporal aspirate in ischemic priapism shows dark, deoxygenated blood. Subsequent aspirations will show brighter blood as corpus cavernosum is reoxygenated by inflow. Empty syringes are from successive injections of phenylephrine. B, A butterfly needle for aspiration and injection should be placed at the penoscrotal junction. Initial attempts in the emergency department failed to reverse priapism because of distal placement of the butterfly needle and failure to repeat aspiration and injections of an α -adrenergic agent.

Figure 28-5. A, Examination of the crural bodies is required when searching for arterial sinusoidal fistula after straddle injury. B, Color Doppler image of arterial sinusoidal fistula of left cavernous artery.

Figure 28-6. A, T2-weighted magnetic resonance image showing cavernous body thrombosis. B, Same patient. There is no enhancement after gadolinium infusion. At operation, extensive smooth muscle necrosis and thrombus were found. Patient had untreated ischemic priapism lasting several days. (Courtesy David Ralph.)

hours, and each had failed medical and surgical interventions. Patients underwent MRI to characterize the extent of smooth muscle necrosis before placement of penile prosthesis (Fig. 28-6). The third role for MRI would be in the imaging of corporal malignancy or metastasis with corporal smooth muscle replaced by malignant tissue or with true ischemic priapism caused by obstruction of venous outflow.

MEDICAL TREATMENTS

Ischemic Priapism

Historically, first aid was applied by the patient or recommended by a health practitioner unfamiliar with the hemodynamics of priapism; these interventions included ejaculation, ice packs, cold

KEY POINTS: PRIAPISM IMAGING

- CDU is an adjunct to the corporal aspirate in differentiating ischemic from nonischemic priapism.
- CDU imaging should include corporal shaft and transperineal assessment of the crural bodies when there is a history of penile trauma or straddle injury.
- CDU should always be considered in the evaluation of a persistent or partial erection after treatments for ischemic priapism.
- Penile arteriography is too invasive as a diagnostic procedure to differentiate ischemic from nonischemic priapism.
- MRI has three possible roles: imaging of a well-established arteriolar-sinusoidal fistula, identifying corporal thrombus, and identifying corporal metastasis.

baths, and cold water enemas. Each of these remedies was thought to end erection by inducing vasoconstriction. Some historical reports advised voiding and exercise. Oral sympathomimetic drugs (etilefrine, pseudoephedrine, phenylpropanolamine, and terbutaline) have been reported to effectively reverse prolonged erection (<4 hours) initiated by ICI therapies with efficacies of 28% to 36% (Lowe and Jarow, 1993). Lowe and Jarow (1993) compared oral terbutaline with pseudoephedrine or placebo in 75 patients with prolonged erection induced by ICI of alprostadil; they reported detumescence in 38% of cases with terbutaline, 28% with pseudoephedrine, and 12% with placebo. In a follow-up study Priyadarshi (2004) specifically investigated the efficacy of oral terbutaline in the management of prolonged erection after ICI (papaverine/chlorpromazine); he administered oral terbutaline 5 mg or placebo to men with persisting erection for more than 2.5 hours. Detumescence was achieved in 42% and 15% of cases, respectively, treated with terbutaline or placebo. Terbutaline treatment was unsuccessful in 58% of cases; all of those patients responded to ICI of an α -adrenergic agent.

Every practice administering diagnostic ICI or teaching ICI must be prepared to manage priapism. In my experience, when a vasoactive injection results in a prolonged erection with duration longer than 1 hour but shorter than 4 hours, aspiration may not be necessary. Phenylephrine (200 μ g) injected with an ultrafine needle and 1-mL syringe may reverse the erection. Reversing a prolonged erection will spare the patient and the office staff the complexity of treating full-blown ischemic priapism.

Oral agents are not recommended in the management of acute ischemic priapism (>4 hours). The recommended initial treatment of ischemic priapism is the decompression of the CC by aspiration. Aspiration will immediately soften the erection and relieve pain. Aspiration alone may relieve priapism in 36% of cases. The AUA Guidelines Panel (2003) advised that there were not sufficient data to conclude that aspiration followed by saline intracorporal irrigation was any more effective than aspiration alone (Montague et al, 2003). Subsequently, Ateyah and colleagues (2005) reported that a combination of corporal blood aspiration and cold saline irrigation effectively terminated priapism in 66% of cases compared with aspiration alone (24%). Data to support the efficacy of cold saline are limited. Aspiration should be repeated until no more dark blood can be seen coming out from the corpora and fresh bright red blood is obtained. This process leads to a marked decrease in the intracavernous pressure, relieves pain, and resuscitates the corporal environment, removing anoxic, acidotic, and hypercarbic blood. A single, large-bore, 19-gauge needle should be inserted at the penoscrotal junction at the 3 or 9 o'clock position to avoid piercing the dorsal neurovascular bundle. The surgeon should compress the penile shaft between the thumb and first digit, just below the 19-gauge needle, aspirating the shaft until it is soft. With the needle left in place, the shaft is permitted to refill. Compression is reapplied and aspiration repeated. These maneuvers may need to be serially

repeated. Several small, empty syringes should be available (3-mL to 12-mL syringes).

Corporal aspiration, if unsuccessful, should be followed by α -adrenergic injection or irrigation. Aspiration followed by the ICI of sympathomimetic drugs was recommended by the AUA Guidelines Panel in 2003 (Montague et al, 2003; Broderick et al, 2010). Sympathomimetic drugs (phenylephrine, etilefrine, ephedrine, epinephrine, norepinephrine, metaraminol) cause cavernous smooth muscle contraction. In the laboratory, normal cavernous smooth muscle preparations from humans, rabbits, and rodents show concentration-dependent contractions on exposure to phenylephrine, if the corporal environment is well oxygenated and has a normal pH (Broderick et al, 1994). In patients, time-dependent changes in the corporeal environment begin within 6 hours of persistent erection (Broderick and Harkaway, 1994). Animal models of ischemic priapism have demonstrated impairment in smooth muscle contraction with progressive acidosis, hypoxia, and glucopenia (Broderick, 1994; Saenz de Tejada et al, 1997; Munnarriz et al, 2006; Muneer et al, 2008). Corpus cavernosum specimens from patients with prolonged priapism show no contractions to high-dose phenylephrine in vitro.

Phenylephrine is a relatively selective α_1 -adrenergic receptor agonist with minimal β -mediated inotropic and chronotropic cardiac effects; it is the agent of choice according to AUA consensus recommendation (2003), the International Consultation on Sexual Medicine (2010), and the European Association of Urology guideline on priapism (2014) (Montague et al, 2003; Broderick et al, 2010; Salonia et al, 2014). There are no comparative trials of sympathomimetics in the management of priapism, nor are there studies of dosage tolerance to report. In terms of corporal physiology, α -adrenergic agonists are vasoconstrictors of cavernous artery and arterioles. Intracavernous administration of an α -adrenergic agent should contract cavernous smooth muscles, allowing sinusoidal blood to egress from subtunical veins. On the other hand, a β -adrenergic agonist, which would relax cavernous smooth muscle and dilate the cavernous artery and arterioles, could promote oxygenated arteriolar blood to enter the cavernous spaces and wash out deoxygenated blood. Metaraminol is a pure α -adrenergic agent; etilefrine, phenylephrine, and epinephrine are mixed α - and β -adrenergic agonists. Terbutaline is a pure β agonist. Case reports with these agents show varying efficacy from 43% to 81%. In addition to the specific reversal agent, there is clearly a time-dependent efficacy for pharmacologic reversal of priapism. For acute pharmacologic management of ischemic priapism, the intracavernous administration of dilute solutions of phenylephrine or epinephrine is most commonly described in the United States. In Europe etilefrine is commonly described. Etilefrine is a phenylephrine related β -adrenergic and α -adrenergic agonist. It is available in oral and parenteral formulations internationally (effortil, ethyladrianol, ethylphenylephrine, phetanol, ethyl nor-adrianol). Currently, pseudoephedrine, phenylpropanolamine, and ephedrine are the orally active adrenergic agents available in the United States. Pseudoephedrine (Sudafed) is regulated under the Combat Methamphetamine Epidemic Act of 2005, which banned over-the-counter sales of cold medicines containing pseudoephedrine. It is available "behind the counter" without a prescription. Neither Sudafed (pseudoephedrine) nor Sudafed PE (phenylephrine) have been evaluated as oral agents for the reversal or prevention of priapism in the United States. Phenylephrine is typically diluted in normal saline to a concentration of 100 to 200 μ g/mL; it is administered intracavernously as a 1-mL injection every 3 to 5 minutes. Administration should be intermittent over the course of an hour. In my experience, phenylephrine can be concentrated as 200 μ g/mL in saline and administered intermittently as 0.5 mL to 1.0 mL every 5 to 10 minutes to a maximum dosage of 1 mg. This will permit up to 10 separate injections of 0.5 mL (100 μ g each) or 5 separate injections of 1 mL (200 μ g each). The penis is aspirated between successive injections by tightly pinching the shaft at the penoscrotal junction, just below the site of needle insertion. Aspiration should continue until the distal shaft is empty and collapses. This removes deoxygenated

acidic blood. Then phenylephrine is injected. Gradually the compression at the penoscrotal junction is released, allowing the shaft to refill with fresh blood. Extremes of age and preexisting cardiovascular diseases should be taken into consideration before intracavernous sympathomimetic administration. Serial monitoring of blood pressure and pulse should be performed during and immediately after ICI of sympathomimetic drugs. Potential side effects of intracavernous sympathomimetics include headache, dizziness, hypertension, reflex bradycardia, tachycardia, and irregular cardiac rhythms. Davila and colleagues (2008) reported subarachnoid hemorrhage in a patient with SCD ischemic priapism. The patient was a 24-year-old African-American man who reported sudden and severe headache immediately after intracorporal administration of phenylephrine 500 µg/mL repeated every 3 minutes for a total of 4 mL (2000 µg = 2 mg). In 2005 the Pennsylvania Patient Safety Authority published an advisory, *Let's Stop This "Epi"demio! Preventing Errors with Epinephrine*. The report

describes a case of a 16-year-old boy who received 4 mL of undiluted 1:1000 epinephrine solution intracavernously to treat priapism. The physician thought the 1:1000 ratio on the epinephrine 1 mg/mL label meant the solution had been prediluted with 1000 mL of fluid (Pennsylvania Patient Safety Authority, 2006). Whichever intracavernous sympathomimetic agent is chosen for the management of ischemic priapism, urologists are well advised to consult their pharmacies and develop clear mixing and dosage protocols for safe administration (Fig. 28-7).

SCD and hematologic malignancies are rare but important causes of ischemic priapism. Classically, treatment of SCD-induced ischemic priapism involved analgesics, hydration, oxygen, bicarbonate, and exchange transfusion. Unfortunately, acute neurologic complications may follow exchange transfusions. Hematologists have begun to question the emphasis on intravenous hydration, sodium bicarbonate for alkalization, and exchange transfusion as first line therapy for SCD-associated priapism (Kato, 2012).

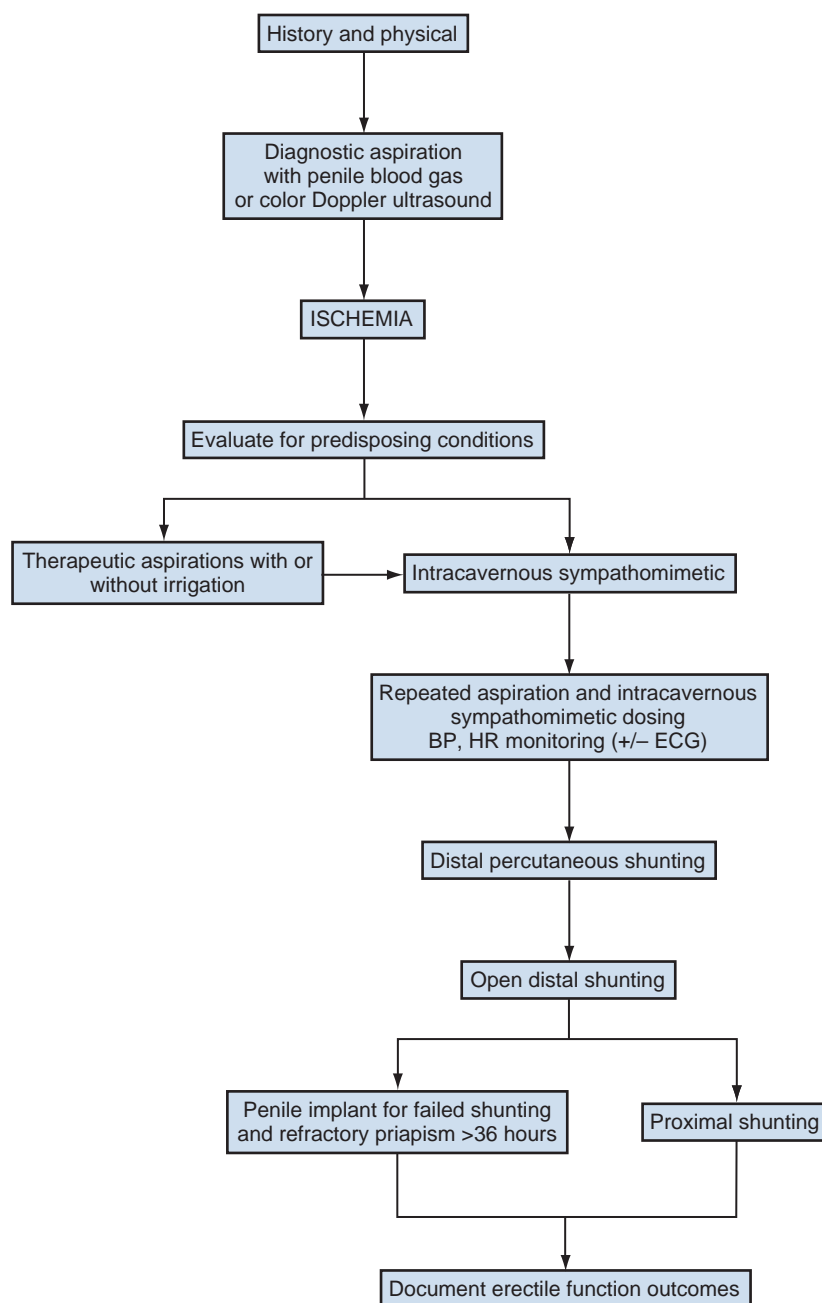

Figure 28-7. Algorithm for managing ischemic priapism. BP, blood pressure; ECG, electrocardiogram; HR, heart rate.

Hydroxycarbamide (hydroxyurea) is a hematologic agent used in the management of vaso-occlusive crises in sickle cell patients (Saad et al, 2004; Morrison and Burnett, 2012). The proposed mechanisms of action are increase in production of hemoglobin F; reduction of leukocytes, platelets, and reticulocytes; and promotion of release of NO. **In the best interests of the patient, the urologist should seek hematologic consultation in the management of boys and men with SCD priapism but remain assertive that hematologic therapy alone is not effective management of SCD priapism (Rogers, 2005).** A 2006 report suggested that blood transfusion may have no effective role in the treatment of sickle cell-induced priapism (Merritt et al, 2006). **Reports from hematology centers suggest high success rates with use of penile aspiration, injection, and irrigation with intracavernous sympathomimetics for SCD priapism (Mantadakis et al, 2000).** Mantadakis and colleagues (2000) conducted a prospective trial for the management of children with SCD with prolonged erection, ages 3 to 18 years (no placebo group). For erections lasting longer than 4 hours and less than 12 hours, emergency department interventions were local anesthetic, cavernous aspiration, and irrigation with 10 mL of a 1:1,000,000 solution of epinephrine. If detumescence lasted for 30 minutes, patients were discharged to home. They described 15 patients receiving 39 interventions, of which 37 were successful; 67% required only one aspiration and irrigation treatment. **In the management of SCD pediatric patients with stuttering priapism, several levels of escalating intervention are necessary, with parental and emergency department staff education being the first level.** Gbadoe and colleagues (2001) described the treatment of 11 SCD patients (ages 30 months to 15 years) with acute ischemic priapism or stuttering priapism. In their series of cases, if the patient had priapism lasting less than 6 hours, aspiration and injection of 5 mg of etilefrine was given in the emergency department; for stuttering priapism, patients were given oral etilefrine 0.5 mg/kg nightly for 1 month, or 0.25 mg/kg twice daily. Patients (parents) also administered injections at home to reverse painful erection lasting longer than 1 hour. The authors reported no significant hypertension and only one case of "agitation" attributed to daily administration.

Stuttering Priapism

Various factors need to be considered in treating stuttering priapism. **Although an episode may last less than 4 hours, increasing frequency or duration of stuttering episodes may herald a major ischemic priapism.** Multiple frequent visits to the emergency department to resolve the priapism are disruptive to the patient's life and embarrassing. If attacks follow sexual activity, patients may become sexually avoidant (Adeyolu et al, 2002; Chow and Payne, 2008). Safety and efficacy of various treatments are poorly characterized in the literature. The side effects of recommended medications should be understood by the patient. Patients on chronic medical therapy to decrease the frequency of stuttering episodes may significantly benefit from performing a single sympathomimetic intracorporal injection at home as part of a personal treatment algorithm (Virag et al, 1996; Teloken et al, 2005). Multiple treatment options have been described: oral and injectable α -adrenergic agonists, terbutaline, digoxin, the antisickling agent hydroxycarbamide (hydroxyurea), estrogens, gonadotropin-releasing hormone (GnRH) analogues, antiandrogens, baclofen, gabapentin, and recently PDE5 inhibitors (Chow and Payne, 2008).

Etilefrine is available as an oral or injectable treatment in some European countries. The maximum oral dose is 100 mg in 24 hours (Okpala et al, 2002). Okpala and colleagues (2002) followed 18 adults (17 SCD patients and 1 with sickle trait), all with a history of stuttering priapism. Patients were given oral etilefrine in escalating doses from 25 mg at bedtime to a maximum of 100 mg each day. Stuttering episodes were reduced in frequency and duration in 72%. A small series of 6 SCD children were followed with administration twice daily with 0.25 mg of etilefrine per kilogram (Gbadoe et al, 2002). **The experience of multiple**

KEY POINTS: MEDICAL MANAGEMENT OF ISCHEMIC PRIAPISM

- Oral therapy is not recommended for the treatment of acute ischemic priapism.
- The initial treatment of ischemic priapism is decompression by aspiration.
- Aspiration should be repeated until oxygenated blood is seen to refill the corpora.
- Aspiration should be followed by the ICI (or irrigation) of a diluted α -adrenergic drug.
- Worldwide availability of adrenergic agents varies; effective reversal of priapism has been documented with dilute injections of ephedrine, epinephrine, etilefrine, metaraminol, or phenylephrine. Phenylephrine is the agent of choice recommended by AUA, International Consultation on Sexual Medicine, and European Association of Urology guidelines.
- Clinicians are advised to consult their pharmacies and develop clear mixing and dosage protocols for safe administration of adrenergic solutions.
- Phenylephrine is a sympathomimetic drug with selective α_1 adrenergic receptor actions; it has minimal β -mediated ionotropic and chronotropic cardiac effects.
- Phenylephrine should be concentrated as 200 μ g/mL in normal saline and administered intracavernously as 0.5 mL to 1 mL. Lower concentrations should be used in children and adults with cardiovascular disease. Administration and aspiration may need to be repeated. No recommendations can be made about maximum safe dosage. Hypertensive stroke has been reported as a complication of cumulative administration of 2 mg.
- Physicians should monitor patients for subjective complaints and objective findings consistent with known undesirable effects: headache, chest discomfort, acute hypertension, reflex bradycardia, tachycardia, palpitations, and cardiac arrhythmia. Patients and parents should be informed about these potential complications.
- Blood pressure monitoring is recommended with repeated sympathomimetic administration. In patients with significant cardiovascular risks, electrocardiogram monitoring is recommended.
- Ischemic priapism associated with SCD requires intracavernous treatment. A hematologist may provide concurrent systemic therapies (oxygen, hydration, transfusion), but the best resolution rates are achieved with therapies directed at the penis.

investigators using oral α -adrenergics in the management of SCD stuttering ischemic priapism suggests that limited daily administration should be considered in the management of stuttering priapism; drug therapy is typically initiated at bedtime. Oral α -adrenergic administration is a preventative strategy for stuttering priapism.

Hormonal Therapies

The primary action of systemic hormonal therapy in stuttering priapism is the suppression of the androgenic effects on penile erection. Attempts to treat stuttering priapism with hormones have exploited known regulators of male sexual function by targeting the pituitary gland (GnRH agonists), suppressing pituitary function through feedback inhibition (diethylstilbestrol [DES]), blocking androgen receptors (antiandrogens), and reducing testicular and adrenal synthesis (ketoconazole). The common goal of hormonal therapy in the prevention of stuttering priapism is to reduce serum testosterone to hypogonadal levels or block testosterone's effects on the penis. In the only randomized placebo-controlled trial, a synthetic estrogen, DES, caused termination of the stuttering
